(c) In both gels, the $\sigma = -0.115$ lane has two bands, one a highly supercoiled DNA and one relaxed. Propose a reason for the presence of relaxed DNA in these lanes (and others).
(d) The native DNA (leftmost lane in each gel) is the same DNA circle isolated from bacterial cells and untreated. What is the approximate superhelical density of this native DNA?

16. Nucleosomes The human genome comprises just over 3.1 billion base pairs. Assuming it contains nucleosomes that are spaced as described in this chapter, how many molecules of histone H2A are present in one somatic human cell? (Ignore reductions in H2A due to its replacement in some regions by H2A variants.) How would the number change after DNA replication but before cell division?

17. Bacterial DNA Topoisomerase IV The gene encoding topoisomerase IV in *E. coli* is essential, even though another type II topoisomerase (topoisomerase II or gyrase) is present. Suggest a reason for the requirement for topoisomerase IV.

18. Chromosome Topology Eukaryotic chromosomes are linear DNA molecules, yet the DNA of a chromosome retains a high level of underwinding (supercoiling) throughout its length. How does the organization of chromosomal DNA into loops called TADs contribute to the maintenance of supercoiling?

DATA ANALYSIS PROBLEM

19. Defining the Functional Elements of Yeast Chromosomes Figure 24-7 shows the major structural elements of a chromosome of budding yeast (*S. cerevisiae*). Heiter, Mann, Snyder, and Davis (1985) determined the properties of some of these elements. They based their study on the finding that in yeast cells, plasmids (which have genes and an origin of replication) act differently from chromosomes (which have these elements plus centromeres and telomeres) during mitosis. The plasmids are not manipulated by the mitotic apparatus and segregate randomly between daughter cells. Without a selectable marker to force the host cells to retain them (see Fig. 9-4), these plasmids are rapidly lost. In contrast, chromosomes, even without a selectable marker, are manipulated by the mitotic apparatus and are lost at a very low frequency (about 10^{-5} per cell division).

Heiter and colleagues set out to determine the important components of yeast chromosomes by constructing plasmids with various parts of chromosomes and observing whether these "synthetic chromosomes" segregated properly during mitosis. To measure the frequencies of different types of failed chromosome segregation, the researchers needed a rapid assay to determine the number of copies of synthetic chromosomes present in different cells. The assay took advantage of the fact that wild-type yeast colonies are white whereas certain adenine-requiring (ade$^-$) mutants yield red colonies on nutrient media; *ade2*$^-$ cells lack functional AIR carboxylase (the enzyme of step 6a in Fig. 22-35) and accumulate AIR (5-aminoimidazole ribonucleotide) in their cytoplasm, and the excess AIR is converted to a conspicuous red pigment. The other part of the assay involved the gene *SUP11*, which encodes an ochre suppressor (a type of nonsense suppressor in which a termination codon specifies an amino acid) that suppresses the phenotype of some *ade2*$^-$ mutants.

Heiter and coworkers started with a diploid strain of yeast homozygous for *ade2*$^-$; these cells are red. When the mutant cells contain one copy of *SUP11*, the metabolic defect is partly suppressed and the cells are pink. When the cells contain two or more copies of *SUP11*, the defect is completely suppressed and the cells are white.

The researchers inserted one copy of *SUP11* into synthetic chromosomes containing various elements thought to be important in chromosome function, and then observed how well these chromosomes were passed from one generation to the next. These pink cells were plated on nonselective media, and the behavior of the synthetic chromosomes was observed. Heiter and coworkers looked for colonies in which the synthetic chromosomes segregated improperly at the first division after plating, giving rise to a colony that was half one genotype and half the other. Because yeast cells are nonmotile, this would be a sectored colony, with one half one color and the other half another color.

(a) One way for the mitotic process to fail is *nondisjunction*: the chromosome replicates but the sister chromatids fail to separate, so both copies of the chromosome end up in the same daughter cell. Explain how nondisjunction of the synthetic chromosome would give rise to a colony that is half red and half white.

(b) Another way for the mitotic process to fail is *chromosome loss*: the chromosome does not enter the daughter nucleus or is not replicated. Explain how loss of the synthetic chromosome would give rise to a colony that is half red and half pink.

By counting the frequency of the different colony types, Heiter and colleagues could estimate the frequency of these aberrant mitotic events with different types of synthetic chromosome. First, they explored the requirement for centromeric sequences by constructing synthetic chromosomes with DNA fragments of different sizes containing a known centromere. Their results are shown here.

Synthetic chromosome	Size of centromere-containing fragment (kbp)	Chromosome loss (%)	Nondisjunction (%)
1	None	—	>50
2	0.63	1.6	1.1
3	1.6	1.9	0.4
4	3.0	1.7	0.35
5	6.0	1.6	0.35

(c) Based on these data, what can you conclude about the size of the centromere required for normal mitotic segregation? Explain your reasoning.

(d) All the synthetic chromosomes created in these experiments were circular and lacked telomeres. Explain how they could be replicated more-or-less properly.

Heiter and colleagues next constructed a series of linear synthetic chromosomes that included the functional centromeric sequence and telomeres, and they measured the total mitotic error frequency (% loss + % nondisjunction) as a function of size.

Synthetic chromosome	Size (kbp)	Total error frequency (%)
6	15	11.0
7	55	1.5
8	95	0.44
9	137	0.14

(e) Based on these data, what can you conclude about the chromosome size required for normal mitotic segregation? Explain your reasoning.

(f) Normal yeast chromosomes are linear, range from 250 kbp to 2,000 kbp in length, and, as noted above, have a mitotic error frequency of about 10^{-5} per cell division. Extrapolating the results from (e), do the centromeric and telomeric sequences used in these experiments explain the mitotic stability of normal yeast chromosomes, or must other elements be involved? Explain your reasoning. (Hint: A plot of log of error frequency vs. length will be helpful.)

Chapter 25

DNA METABOLISM

25.1 DNA Replication *915*
25.2 DNA Repair *930*
25.3 DNA Recombination *940*

As the repository of genetic information, DNA occupies a unique and central place among biological macromolecules. The nucleotide sequences of DNA encode the primary structures of all cellular RNAs and proteins and, through enzymes, indirectly affect the synthesis of all other cellular constituents. This passage of information from DNA to RNA and protein guides the size, shape, and functioning of every living thing.

DNA is a marvelous device for the stable storage of genetic information. The phrase "stable storage," however, conveys a static and misleading picture. It fails to capture the complexity of processes by which genetic information is preserved in an uncorrupted state and then transmitted from one generation of cells to the next. DNA metabolism comprises both the process that gives rise to faithful copies of DNA molecules (replication) and the processes that affect the inherent structure of the information (repair and recombination). Together, these activities are both the focus of this chapter and the underpinning for several guiding principles:

P1 **Along with catalysis, biological information is one of the two key prerequisites for life.** The faithful maintenance and transmission of genetic information from one generation to another ensures continuity within each species.

P2 **Information is expensive.** The chemistry of joining one nucleotide to the next in DNA replication is elegant and simple, almost deceptively so. However, the enzymatic and thermodynamic commitment to linking one nucleotide to another in DNA far exceeds what would normally be required to successfully form a phosphodiester bond. It is not enough to synthesize a phosphodiester bond; that bond must accurately link two *particular* nucleotides.

P3 **The fidelity of genome maintenance and transmission is not perfect.** DNA damage happens, often by spontaneous processes. DNA replication and repair deal with the vast majority of DNA lesions, providing a high degree of genetic fidelity and stability. The few DNA damage events that slip through uncorrected provide fuel for evolution.

P4 **Although considered separately, the processes of replication, repair, and recombination of DNA are not distinct.** These processes are highly integrated in cells, and they are required for proper genome maintenance.

We give the *enzymes* of DNA metabolism special emphasis in this chapter. These enzymes are not only intrinsically important biologically; they are also important in medicine and biochemical technologies. Many of the seminal discoveries in DNA metabolism have been made with *Escherichia coli*, so its well-understood enzymes are generally used to illustrate the ground rules.

KEY CONVENTION Before taking a closer look at replication, we make a short digression into the use of abbreviations in naming genes and proteins — you will encounter many of these in this and later chapters. Bacterial genes generally are named using three italicized, lowercase letters that often reflect a gene's apparent function. For example, the *dna*, *uvr*, and *rec* genes affect *DNA* replication, resistance to the damaging effects of *UV* radiation, and *rec*ombination, respectively. Where several genes affect the same process, the letters *A*, *B*, *C*, and so forth, are added — as in *dnaA*, *dnaB*, *dnaQ*, for example — usually reflecting their order of discovery rather than the order of their gene products in a reaction sequence. Similar conventions exist for naming eukaryotic genes, although the exact form of the abbreviations may vary with the species, and no single convention applies to all eukaryotic systems. For example, in the budding yeast *Saccharomyces cerevisiae*, gene names are generally three uppercase letters followed by a number, all italicized (e.g., the gene *COX1* encodes a subunit of cytochrome oxidase). Gene names that predate current conventions may differ in format.

The use of abbreviations in naming proteins is less straightforward. During genetic investigations, the protein product of each gene is usually isolated and characterized. Many bacterial genes were identified and named before the roles of their protein products were understood in detail. Sometimes the gene product was found to be a previously isolated protein, and some renaming occurred. Often, however, the product turned out to be an as yet unknown protein, with an activity not easily described by a simple enzyme name.

Bacterial proteins often retain the name of their genes. When referring to the protein product of an *E. coli* gene, we use roman type and capitalize the first letter: for example, the *dnaA* and *recA* gene products are the DnaA and RecA proteins, respectively. Conventions for eukaryotic proteins are again complex. For yeast, some proteins have long common names (such as cytochrome oxidase). Others have the same name as the gene, in which case the protein name usually has one uppercase and two lowercase letters, followed by a number and the letter "p," all in roman type (such as Rad51p). The "p" is to emphasize that this is a protein and to prevent confusion with naming conventions for other organisms. ■

25.1 DNA Replication

P1 Long before the structure of DNA was known, scientists wondered at the ability of organisms to create faithful copies of themselves and, later, at the ability of cells to produce many identical copies of large, complex macromolecules. Speculation about these problems centered around the concept of a **template**, a structure that would allow molecules to be lined up in a specific order and joined to create a macromolecule with a unique sequence and function. The 1940s brought the revelation that DNA was the genetic molecule, but not until James Watson and Francis Crick deduced its structure did the way in which DNA could act as a template for the replication and transmission of genetic information become clear: *one strand is the complement of the other.* The strict base-pairing rules mean that each strand provides the template for a new strand with a predictable and complementary sequence (see Figs. 8-14, 8-15). The fundamental properties of the DNA replication process and the mechanisms used by the enzymes that catalyze it have proved to be essentially identical in all species.

DNA Replication Follows a Set of Fundamental Rules

Early research on bacterial DNA replication and its enzymes helped to establish several basic properties that have proven applicable to DNA synthesis in every organism.

DNA Replication Is Semiconservative **P1** Each DNA strand serves as a template for the synthesis of a new strand, producing two new DNA molecules, each with one new strand and one old strand. This is **semiconservative replication**. The semiconservative nature of replication was established by Matthew Meselson and Frank Stahl in 1957.

Replication Begins at an Origin and Usually Proceeds Bidirectionally Following the confirmation of a semiconservative mechanism of replication, a host of questions arose. Are the parent DNA strands completely unwound before each is replicated? Does replication begin at random places or at a unique point? After initiation at any point in the DNA, does replication proceed in one direction or both?

Photographic images of tritium (^{3}H)–labeled bacterial DNA made by John Cairns revealed that the intact chromosome of *E. coli* is a single huge circle, 1.7 mm long. Radioactive DNA isolated from cells during replication showed an extra loop (**Fig. 25-1**). Cairns concluded that the loop resulted from the formation of two radioactive daughter strands, each complementary to a parent

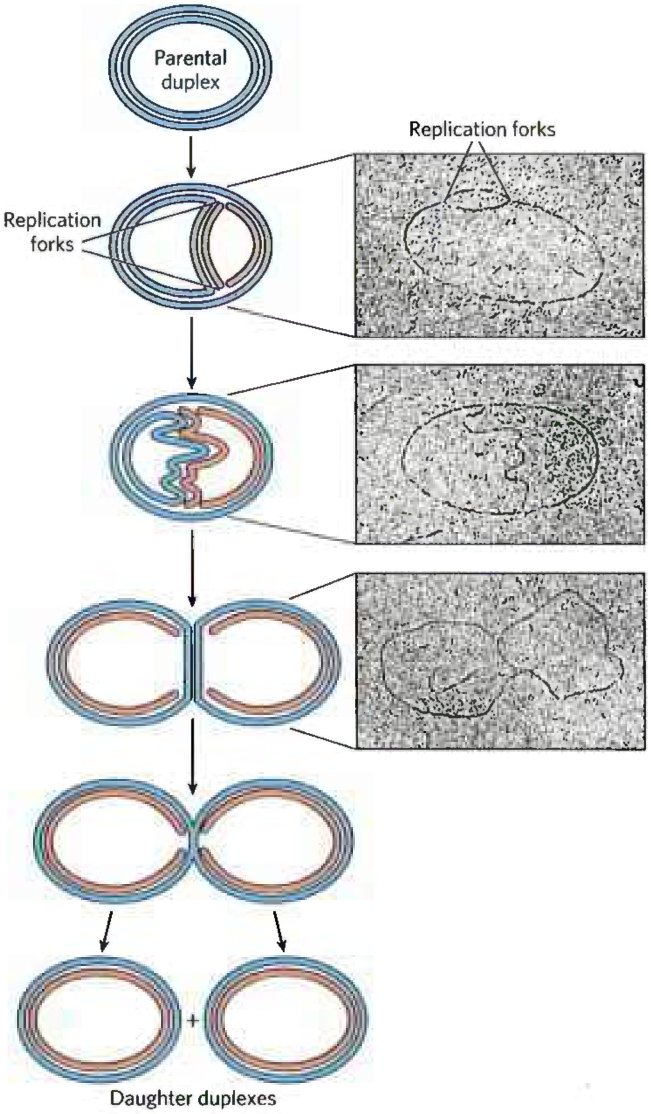

FIGURE 25-1 Visualization of DNA replication. Stages in the replication of circular DNA molecules have been visualized by electron microscopy. Replication of a circular chromosome produces a structure resembling the Greek letter theta, θ, as both strands are replicated simultaneously (new strands shown in light red). The electron micrographs show images of plasmid DNA being replicated from a single replication origin. [Electron micrographs: Cairns, J. (1963), The Chromosome of *Escherichia coli*, *Cold Spring Harbor Symp Quant Biol*, 28, 43–46. © Cold Spring Harbor Laboratory Press.]

strand. One or both ends of the loop are dynamic points, termed **replication forks**, where parent DNA is being unwound and the separated strands quickly replicated. Cairns's results demonstrated that both DNA strands are replicated simultaneously, and variations on his experiment showed that replication of bacterial chromosomes is bidirectional: both ends of the loop have active replication forks.

Determination of whether the replication loops originate at a unique point in the DNA required landmarks along the DNA molecule. These landmarks were provided by a technique called **denaturation mapping**, developed by Ross Inman and colleagues. Using the 48,502 bp chromosome of bacteriophage λ, Inman showed that DNA could be selectively denatured at sequences unusually rich in A=T base pairs, generating a reproducible pattern of single-strand bubbles (see Fig. 8-28). Using the denatured regions as points of reference, investigators have subsequently been able to measure the position and progress of the replication forks. Inman and colleagues found that the replication loops always initiated at a unique point, which was termed an **origin**. They also confirmed the earlier observation that replication is usually bidirectional. For circular DNA molecules, the two replication forks meet at a point on the side of the circle opposite to the origin. Specific origins of replication have since been identified and characterized in bacteria and eukaryotes.

DNA Synthesis Proceeds in a 5′→3′ Direction and Is Semidiscontinuous A new strand of DNA is always synthesized in the 5′→3′ direction, with the free 3′-OH as the point at which the DNA is elongated. (Recall from Chapter 8 that the 5′ end lacks a nucleotide attached to the 5′ position, and the 3′ end lacks a nucleotide attached to the 3′ position.) Because the two DNA strands are antiparallel, the strand serving as the template is read from its 3′ end toward its 5′ end.

If synthesis always proceeds in the 5′→3′ direction, how can both strands be synthesized simultaneously? If both strands were synthesized *continuously* while the replication fork moved, one strand would have to undergo 3′→5′ synthesis. This problem was resolved by Reiji Okazaki and colleagues in the 1960s. Okazaki found that one of the new DNA strands is synthesized in short pieces, now called **Okazaki fragments**. Thus, one strand is synthesized continuously and the other discontinuously (Fig. 25-2). The continuous strand, or **leading strand**, is the one for which 5′→3′ synthesis proceeds in the *same* direction that the replication fork moves. The discontinuous strand, or **lagging strand**, is the one in which 5′→3′ synthesis proceeds in the direction *opposite* to the direction of fork movement. Okazaki fragments are typically 150 to 200 nucleotides long in eukaryotes, and 1,000 to 2,000 nucleotides long in bacteria. As we shall see, leading and lagging strand syntheses are tightly coordinated.

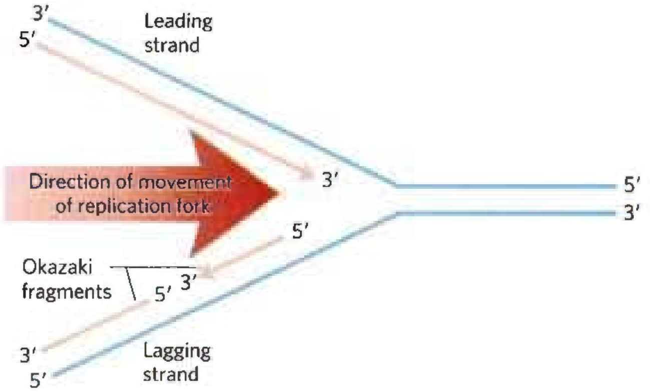

FIGURE 25-2 Defining DNA strands at the replication fork. A new DNA strand (light red) is always synthesized in the 5′→3′ direction. The template is read in the opposite direction, 3′→5′. The leading strand is continuously synthesized in the direction taken by the replication fork. The other strand, the lagging strand, is synthesized discontinuously in short pieces (Okazaki fragments) in a direction opposite to that in which the replication fork moves. The Okazaki fragments are spliced together by DNA ligase. In bacteria, Okazaki fragments are ~1,000 to 2,000 nucleotides long. In eukaryotic cells, they are 150 to 200 nucleotides long.

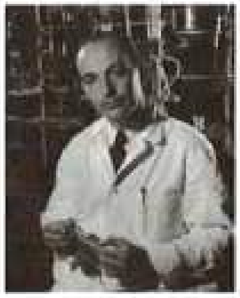
DNA Is Degraded by Nucleases

To explain the enzymology of DNA replication, we first introduce the enzymes that degrade DNA rather than synthesize it. These enzymes are known as **nucleases**, or **DNases** if they are specific for DNA rather than RNA. Every cell contains several different nucleases, belonging to two broad classes: exonucleases and endonucleases. **Exonucleases** degrade nucleic acids from one end of the molecule. Many operate in only the 5′→3′ direction or the 3′→5′ direction, removing nucleotides only from the 5′ end or the 3′ end, respectively, of one strand of a double-stranded nucleic acid or of a single-stranded DNA. **Endonucleases** can begin to degrade at specific internal sites in a nucleic acid strand or molecule, reducing it to smaller and smaller fragments. A few exonucleases and endonucleases degrade only single-stranded DNA. A few important classes of endonucleases cleave only at specific nucleotide sequences (such as the restriction endonucleases that are so important in biotechnology; see Chapter 9, Fig. 9-2). You will encounter many types of nucleases in this and subsequent chapters.

DNA Is Synthesized by DNA Polymerases



Arthur Kornberg, 1918–2007
[World History Archive/Alamy.]

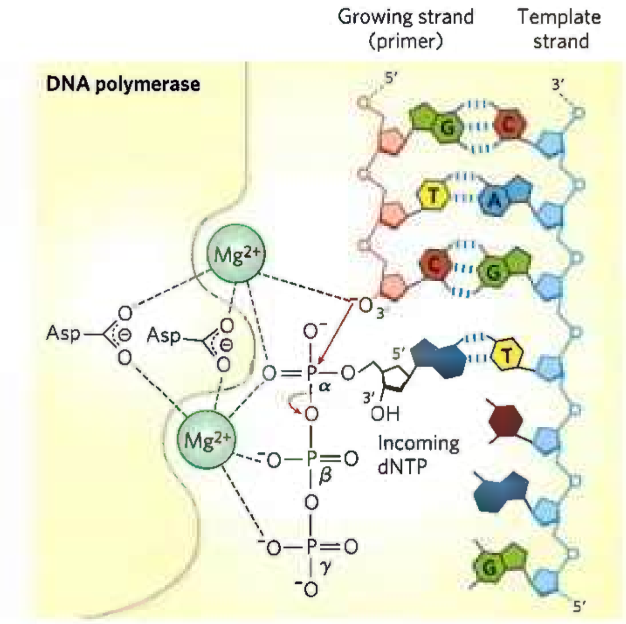
The search for an enzyme that could synthesize DNA began in 1955. Work by Arthur Kornberg and colleagues led to the purification and characterization of a **DNA polymerase** from *E. coli* cells, a single-polypeptide enzyme now called **DNA polymerase I** (M_r 103,000; encoded by the *polA* gene). Much later, investigators found that *E. coli* contains at least four additional distinct DNA polymerases, described below.

Detailed studies of DNA polymerase I revealed features of the DNA synthetic process that are now known to be common to all DNA polymerases. The fundamental reaction is a phosphoryl group transfer. The nucleophile is the 3′-hydroxyl group of the nucleotide at the 3′ end of the growing strand. Nucleophilic attack occurs at the α phosphorus of the incoming deoxynucleoside 5′-triphosphate (**Fig. 25-3**). Inorganic pyrophosphate is released in the reaction. The general reaction is

$$\underset{\text{DNA}}{(\text{dNMP})_n} + \text{dNTP} \longrightarrow \underset{\substack{\text{Lengthened}\\\text{DNA}}}{(\text{dNMP})_{n+1}} + \text{PP}_\text{i} \qquad (25\text{-}1)$$

where dNMP and dNTP are a deoxynucleoside 5′-monophosphate and 5′-triphosphate, respectively. Catalysis by virtually all DNA polymerases prominently involves two Mg^{2+} ions at the active site. One of these helps to deprotonate the 3′-hydroxyl group, rendering it a more effective nucleophile. The other binds to the incoming dNTP and facilitates departure of the pyrophosphate.

P2 The reaction seems to proceed with only a minimal change in free energy, given that one phosphodiester bond is formed at the expense of a somewhat less stable phosphate anhydride. However, noncovalent base-stacking and base-pairing interactions provide additional stabilization to the lengthened DNA product relative to the free nucleotide. Also, the formation of products is facilitated in the cell by the 19 kJ/mol generated in the subsequent hydrolysis of the pyrophosphate product by the enzyme pyrophosphatase (p. 485).



MECHANISM FIGURE 25-3 The DNA polymerase reaction. The catalytic mechanism for addition of a new nucleotide by DNA polymerase involves two Mg^{2+} ions, coordinated to the phosphate groups of the incoming nucleotide triphosphate, the 3′-hydroxyl group that will act as a nucleophile, and three Asp residues, two of which are highly conserved in all DNA polymerases. The Mg^{2+} ion depicted at the top facilitates attack of the 3′-hydroxyl group of the primer on the α phosphate of the nucleotide triphosphate; the other Mg^{2+} ion facilitates displacement of the pyrophosphate. Both ions stabilize the structure of the pentacovalent transition state. RNA polymerases use a similar mechanism.

Early work on DNA polymerase I led to the definition of two central requirements for DNA polymerization (**Fig. 25-4**). First, all DNA polymerases require a template. The polymerization reaction is guided by a template DNA strand according to the base-pairing rules predicted by Watson and Crick: where a guanine is present in the template, a cytosine deoxynucleotide is added to the new strand, and so on. P1 This was a particularly important discovery, not only because it provided a chemical basis for accurate semiconservative DNA replication, but also because it represented the first example of the use of a template to guide a biosynthetic reaction.

Second, the polymerases require a **primer**. A primer is a strand segment (complementary to the template) with a free 3′-hydroxyl group to which a nucleotide can be added; the free 3′ end of the primer is called the **primer terminus** (Fig. 25-4a). In other words, part of the new strand must already be in place: all DNA polymerases can add nucleotides only to a preexisting strand. Many primers are oligonucleotides of RNA rather than DNA, and specialized enzymes synthesize primers when and where they are required.

A DNA polymerase active site has two parts (Fig. 25-4a). The incoming nucleotide is initially positioned in the **insertion site**. Once the phosphodiester bond is formed, the polymerase slides forward on the DNA and the new base pair is positioned in the **postinsertion site**. These sites are located in a pocket that resembles the palm of a hand (Fig. 25-4b, c).

After adding a nucleotide to a growing DNA strand, a DNA polymerase either dissociates or moves along the template and adds another nucleotide. Dissociation and reassociation of the polymerase can limit the overall polymerization rate—the process is generally faster when a polymerase adds more nucleotides without dissociating from the template. The average number of nucleotides added before a polymerase dissociates defines its **processivity**. DNA polymerases vary greatly in processivity; some add just a few nucleotides before dissociating, whereas others add many thousands.

Replication Is Very Accurate

Replication proceeds with an extraordinary degree of fidelity. In *E. coli*, a mistake is made only once for every 10^9 to 10^{10} nucleotides added. For the *E. coli* chromosome of $\sim 4.6 \times 10^6$ bp, this means that an error occurs only once per 1,000 to 10,000 replications. During polymerization, discrimination between correct and incorrect nucleotides relies not just on the hydrogen bonds that specify the correct pairing between complementary bases but also on the common geometry of the standard A=T and G≡C base pairs (**Fig. 25-5**). FIGURE 25-4 Elongation of a DNA chain. (a) DNA polymerase I activity requires a single unpaired strand to act as template and a primer strand to provide the free hydroxyl group at the 3′ end to which the new nucleotide unit is added. Each incoming complementary nucleotide is bound selectively, in part by base-pairing to the appropriate nucleotide in the template strand. The reaction product has a new free 3′ hydroxyl, allowing the addition of another nucleotide. The newly formed base pair translocates to make the active site available to the next pair to be formed. (b) The core of most DNA polymerases is shaped like a human hand that wraps around the active site. The structure shown here is DNA polymerase I of *Thermus aquaticus*, bound to DNA. FIGURE 25-5 Contribution of base-pair geometry to the fidelity of DNA replication. (a) The standard A═T and G≡C base pairs have very similar geometries, and an active site sized to fit one will generally accommodate the other. (b) The geometry of incorrectly paired bases can exclude them from the active site, as occurs on DNA polymerase.

accommodates only base pairs with this geometry. An incorrect nucleotide may be able to hydrogen-bond with a base in the template, but it generally will not fit into the active site. Incorrect bases can be rejected before the phosphodiester bond is formed.

The accuracy of the polymerization reaction itself, however, is insufficient to account for the high degree of fidelity in replication. Careful measurements in vitro have shown that DNA polymerases insert one incorrect nucleotide for every 10^4 to 10^5 correct ones. These mistakes sometimes occur because a base is briefly in an unusual tautomeric form (see Fig. 8-9), allowing it to hydrogen-bond with an incorrect partner. In vivo, the error rate is reduced by additional enzymatic mechanisms.

One mechanism intrinsic to many DNA polymerases is a separate 3′→5′ exonuclease activity that double-checks each nucleotide after it is added. This nuclease activity permits the enzyme to remove a newly added nucleotide and is highly specific for mismatched base pairs (**Fig. 25-6**). If the polymerase has added the wrong nucleotide, translocation of the enzyme to the position where the next nucleotide is to be added is inhibited. This kinetic pause provides the opportunity for a correction. The 3′→5′ exonuclease activity cleaves the most recently added phosphodiester bond and removes the mispaired nucleotide; the polymerase then adds another nucleotide to begin active synthesis again. This activity, known as **proofreading**, is not simply the reverse of the polymerization reaction (Eqn 25-1). P2 Instead, replacement of the incorrect nucleotide requires the expenditure of three high-energy bonds. The polymerizing and proofreading activities of a DNA polymerase can be measured separately. Proofreading improves the inherent accuracy of the polymerization reaction 10^2- to 10^3-fold. In the monomeric DNA polymerase I, the polymerizing and proofreading activities have separate active sites within the same polypeptide.

FIGURE 25-6 An example of error correction by the 3′→5′ exonuclease activity of DNA polymerase I. Structural analysis has located the exonuclease activity behind the polymerase activity as the enzyme is oriented in its movement along the DNA. A mismatched base (here, a C–T mismatch) impedes translocation of DNA polymerase I (Pol I) to the next site.

P3 When base selection and proofreading are combined, DNA polymerase leaves behind one net error for every 10^6 to 10^8 bases added. Yet the measured accuracy of replication in *E. coli* is higher still. The additional accuracy is provided by a separate enzyme system that repairs the mismatched base pairs remaining after replication. We describe this mismatch repair, along with other DNA repair processes, in Section 25.2.

E. coli Has at Least Five DNA Polymerases

More than 90% of the DNA polymerase activity observed in *E. coli* extracts can be accounted for by DNA polymerase I. Soon after the isolation of this enzyme in 1955, however, evidence began to accumulate that it is not suited for replication of the large *E. coli* chromosome. First, the rate at which it adds nucleotides (600 nucleotides/min) is too slow (by a factor of 100 or more) to account for the rates at which the replication fork moves in the bacterial cell. Second, DNA polymerase I has a relatively low processivity. Third, genetic studies have demonstrated that many genes, and therefore many proteins, are involved in replication: DNA polymerase I clearly does not act alone. Fourth, and most important, in 1969 John Cairns isolated a bacterial strain with an altered gene for DNA polymerase I that produced an inactive enzyme. Although this strain was abnormally sensitive to agents that damaged DNA, it was nevertheless viable.

A search for other DNA polymerases led to the discovery of *E. coli* **DNA polymerase II** and **DNA polymerase III** in the early 1970s. DNA polymerase II is an enzyme involved in one type of DNA repair (Section 25.3). DNA polymerase III is the principal replication enzyme in *E. coli*. DNA polymerases IV and V, identified in 1999, are involved in an unusual form of DNA repair (Section 25.2). The properties of these five DNA polymerases are compared in **Table 25-1**.

DNA polymerase I, then, is not the primary enzyme of replication; instead, it performs a host of cleanup functions during replication, recombination, and repair. The polymerase's special functions are enhanced by its 5′→3′ exonuclease activity. This activity, distinct from the 3′→5′ proofreading exonuclease (Fig. 25-6), is

TABLE 25-1 Comparison of the Five DNA Polymerases of *E. coli*

Processivity (nucleotides added before polymerase dissociates)	3–200	1,500	≥500,000	1	6–8

[a] Translesion (mutagenic) DNA polymerases. For DNA polymerase IV, processivity is increased substantially by association with a β clamp. These polymerases are slowed when a DNA lesion is present in the DNA template strand.

[b] For enzymes with more than one subunit, the gene listed here encodes the subunit with polymerization activity. Note that *dnaE* is an earlier designation for the gene now referred to as *polC*.

[c] Polymerization subunit only. DNA polymerase II shares several subunits with DNA polymerase III, including the $\beta, \delta, \delta', \chi$, and ψ subunits (see Table 25-2).

located in a structural domain that can be separated from the rest of the enzyme by mild protease treatment. When the 5′→3′ exonuclease domain is removed, the remaining fragment (M_r 68,000), the **large fragment** or **Klenow fragment**, retains the polymerization and proofreading activities. The 5′→3′ exonuclease activity of intact DNA polymerase I can replace a segment of DNA (or RNA) paired to the template strand, in a process known as nick translation (**Fig. 25-7**). Most other DNA polymerases lack a 5′→3′ exonuclease activity.

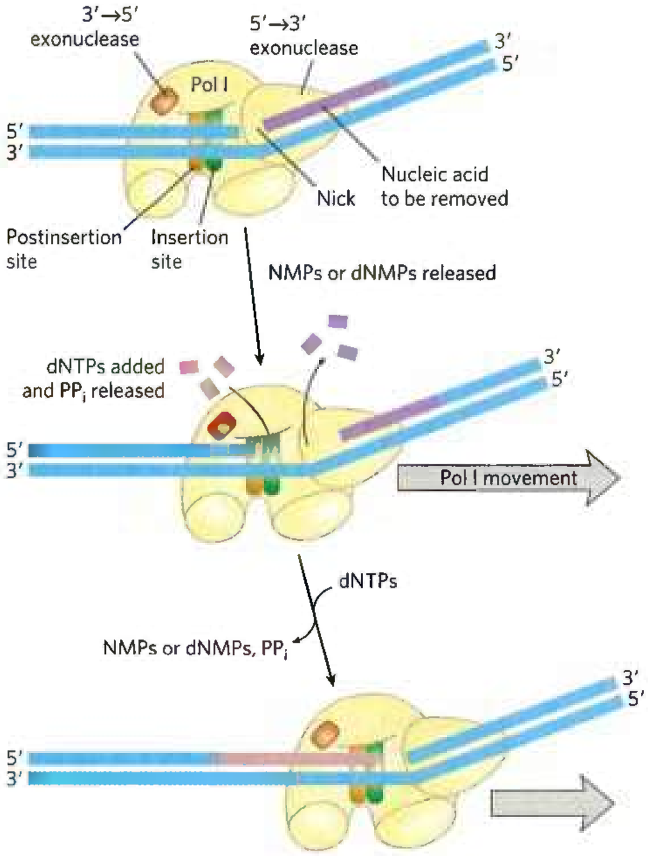

FIGURE 25-7 Nick translation. The bacterial DNA polymerase I has three domains, catalyzing its DNA polymerase, 5′→3′ exonuclease, and 3′→5′ exonuclease activities. The 5′→3′ exonuclease domain is in front of the enzyme as it moves along the DNA and is not shown in Figure 25-4. By degrading the DNA strand ahead of the enzyme and synthesizing a new strand behind, DNA polymerase I can promote nick translation, in which a break or nick in the DNA is effectively moved along with the enzyme. This process has a role in DNA repair and in the removal of RNA primers during replication (both described later in this chapter). The strand of nucleic acid to be removed (either DNA or RNA) is shown in purple, the replacement strand in red. DNA synthesis begins at a nick (a broken phosphodiester bond, leaving a free 3′ hydroxyl and a free 5′ phosphate). A nick remains where DNA polymerase I eventually dissociates, and the nick is later sealed by another enzyme.

DNA polymerase III is much more complex than DNA polymerase I, with nine different kinds of subunits (**Table 25-2**). Its polymerization and proofreading activities reside in its α and ε subunits, respectively. The θ subunit associates with α and ε to form a core polymerase, which can polymerize DNA but with limited processivity. Up to three core polymerases can be linked by a clamp-loading complex consisting of five subunits of three different types, $\tau_3\delta\delta'$. The core polymerases are linked through the τ (tau) subunits. Two additional subunits, χ (chi) and ψ (psi), are bound to the clamp-loading complex. The entire assembly of 16 protein subunits (eight different types) is called DNA polymerase III* (**Fig. 25-8a**).

DNA polymerase III* can polymerize DNA, but with a much lower processivity than one would expect for the organized replication of an entire chromosome. The necessary increase in processivity is provided by the addition of the β subunits. The β subunits associate in pairs to form donut-shaped structures that encircle the DNA and act like clamps (Fig. 25-8b). Each dimer associates with a core subassembly of polymerase III* (one dimeric clamp per active core subassembly) and slides along the DNA as replication proceeds. The β sliding clamp prevents the dissociation of DNA polymerase III from DNA, dramatically increasing processivity—to greater than 500,000

TABLE 25-2 Subunits of DNA Polymerase III of *E. coli*

Subunit	Number of subunits per holoenzyme	M_r of subunit	Gene	Function of subunit	
α	3	129,900	*polC* (*dnaE*)	Polymerization activity	Core polymerase
ε	3	27,500	*dnaQ* (*mutD*)	$3' \rightarrow 5'$ proofreading exonuclease	
θ	3	8,600	*holE*	Stabilization of ε subunit	
τ	3	71,100	*dnaX*	Stable template binding; core enzyme dimerization	Clamp-loading (γ) complex that loads β subunits on lagging strand at each Okazaki fragment[a]
δ	1	38,700	*holA*	Clamp opener	
δ'	1	36,900	*holB*	Clamp loader	
χ	1	16,600	*holC*	Interaction with SSB	
ψ	1	15,200	*holD*	Interaction with τ and χ	
β	6	40,600	*dnaN*	DNA clamp required for optimal processivity	

[a] The γ subunit is encoded by a portion of the gene for the τ subunit (*dnaX*), such that the amino-terminal 66% of the τ subunit has the same amino acid sequence as the γ subunit. The γ subunit is generated by a translational frameshifting mechanism (p. 1013) that leads to premature translational termination. The γ subunit shares the clamp-loading functions of τ but lacks the protein segments that interact with the core polymerase or with DnaB helicase. Clamp-loading complexes incorporating γ subunits may operate independently of the DNA polymerase III holoenzyme, promoting the unloading of β clamps discarded on the lagging strand as the replication fork progresses. They may also promote loading of β clamps for some DNA repair processes that require DNA synthesis away from the replication fork.

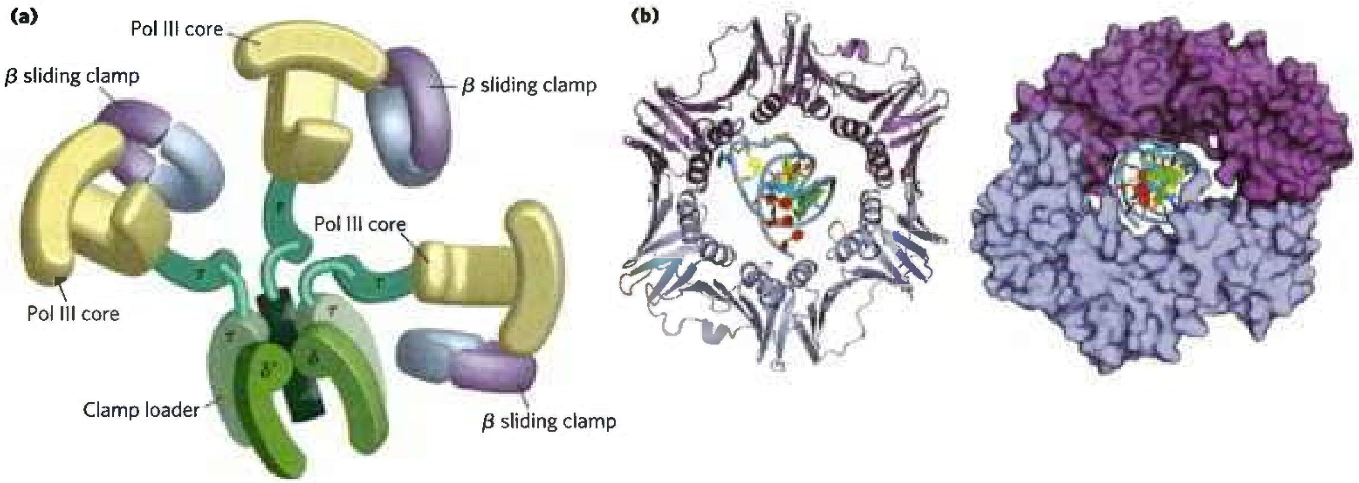

FIGURE 25-8 DNA polymerase III. (a) Architecture of bacterial DNA polymerase III (Pol III). Three core domains, composed of subunits α, ε, and θ, are linked by a five-subunit clamp-loading complex, with the composition $\tau_3\delta\delta'$. The core subunits and clamp-loading complex constitute DNA polymerase III*. The other two subunits of DNA polymerase III*, χ and ψ (not shown), also bind to the clamp-loading complex. Three β clamps interact with the three core subassemblies, each clamp a dimer of the β subunit. The complex interacts with the DnaB helicase (described later in the text) through the τ subunits. (b) Two β subunits of *E. coli* polymerase III form a circular clamp that surrounds the DNA. The clamp slides along the DNA molecule, increasing the processivity of the polymerase III holoenzyme to more than 500,000 nucleotides by preventing its dissociation from the DNA. The two β subunits are shown in two shades of purple as ribbon structures (left) and surface contour images (right), surrounding the DNA. [(a) Information from N. Yao and M. O'Donnell, *Mol. Biosyst.* 4:1075, 2008. (b) Data from PDB ID 2POL, X.-P. Kong et al., *Cell* 69:425, 1992.]

(Table 25-1). The addition of the β subunits converts DNA polymerase III* to DNA polymerase III holoenzyme.

DNA Replication Requires Many Enzymes and Protein Factors

Replication in *E. coli* requires not just a single DNA polymerase but 20 or more different enzymes and proteins, each performing a specific task. The entire complex has been termed the **DNA replicase system** or **replisome**. The enzymatic complexity of replication reflects the constraints imposed by the structure of DNA and by the requirements for accuracy. The main classes of replication enzymes are considered here in terms of the problems they overcome.

The DNA must be separated into two strands that each act as a template. P2 This is generally accomplished by **helicases**, enzymes that move along the DNA and separate the strands, using chemical energy from ATP. Strand separation creates topological stress in the helical DNA structure (see Fig. 24-11), which is relieved by the action of **topoisomerases**. The separated strands are stabilized by **DNA-binding proteins**. As noted earlier, before DNA polymerases can begin synthesizing DNA, primers must be present on the template—generally, short segments of RNA synthesized by enzymes known as **primases**. Ultimately, the RNA primers are removed and replaced by DNA; in *E. coli*, this is one of the many functions of DNA polymerase I. A specialized nuclease that degrades RNA in RNA-DNA hybrids, called RNase H1, also removes some RNA primers. After an RNA primer is removed and the gap is filled in with DNA, a nick remains in the DNA backbone in the form of a broken phosphodiester bond. These nicks are sealed by **DNA ligases**. All these processes require coordination and regulation best characterized in the *E. coli* system.

Replication of the *E. coli* Chromosome Proceeds in Stages

The synthesis of a DNA molecule can be divided into three stages: initiation, elongation, and termination, distinguished both by the reactions taking place and by the enzymes required. As you will find here and in the next two chapters, synthesis of the major information-containing biological polymers — DNAs, RNAs, and proteins — can be understood in terms of these same three stages, with the stages of each pathway having unique characteristics. The events described below reflect information derived primarily from in vitro experiments using purified *E. coli* proteins, although the principles are highly conserved in all replication systems.

Initiation The *E. coli* replication origin, *oriC*, consists of 245 bp and contains DNA sequence elements that are highly conserved among bacterial replication origins. The general arrangement of the conserved sequences is illustrated in Figure 25-9. Two types of sequences are of special interest: five repeats of a 9 bp sequence (R sites) that serve as binding sites for the key initiator protein, DnaA, and a region rich in A=T base pairs called the **DNA unwinding element (DUE)**. There are three additional DnaA-binding sites (I sites), and binding sites for the proteins IHF (integration host factor) and FIS (factor for inversion stimulation). These two proteins were discovered as necessary components of certain recombination reactions described later in this chapter, and their names reflect those roles. Another DNA-binding protein, HU (a histonelike bacterial protein originally dubbed factor U), also participates but does not have a specific binding site.

At least 10 different enzymes or proteins (summarized in Table 25-3) participate in the initiation phase of replication. They open the DNA helix at the origin and establish a prepriming complex for subsequent reactions. The crucial component in the initiation process is the DnaA protein, a member of the **AAA+ ATPase** protein family (*A*TPases *a*ssociated with diverse cellular *a*ctivities). Many AAA+ ATPases, including DnaA, form oligomers and hydrolyze ATP relatively slowly. This ATP hydrolysis acts as a switch that mediates interconversion of the protein between two states. In the case of DnaA, the ATP-bound form is active and the ADP-bound form is inactive.

Eight DnaA protein molecules, all in the ATP-bound state, assemble to form a helical complex encompassing the R and I sites in *oriC* (Fig. 25-10). DnaA has a higher affinity for R sites than I sites, and it binds R sites equally well in its ATP- or ADP-bound form. The I sites, which bind only the ATP-bound DnaA, allow discrimination between the active and inactive forms of DnaA. The tight right-handed wrapping of the DNA around this complex introduces a positive supercoil (see Chapter 24). The associated strain in the nearby DNA, combined with the binding of additional DnaA protein to the DUE region, leads to strand separation in the A=T-rich DUE. The complex formed at the replication origin also includes several DNA-binding proteins—HU, IHF, and FIS—that facilitate DNA bending.

The DnaC protein, another AAA+ ATPase, then loads the DnaB protein onto the separated DNA strands in the denatured region. A hexamer of DnaC, each subunit bound to ATP, forms a tight complex with the ring-shaped, hexameric DnaB helicase. This DnaC-DnaB interaction opens the DnaB ring, the process being aided by a further interaction between DnaB and DnaA. Two of the ring-shaped DnaB hexamers are loaded in the DUE, one onto each DNA strand. The ATP bound to DnaC is hydrolyzed, releasing the DnaC and leaving the DnaB bound to the DNA.

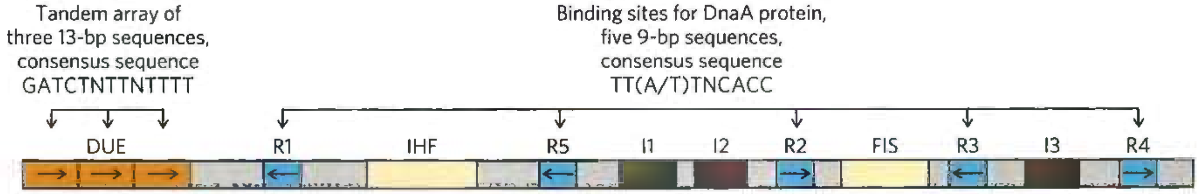

FIGURE 25-9 Arrangement of sequences in the *E. coli* replication origin, *oriC*. Conserved sequences for key repeated elements are shown. N represents any of the four nucleotides. The horizontal arrows indicate the orientations of the nucleotide sequences (left-to-right arrow denotes a sequence in the top strand; right-to-left, in the bottom strand). FIS and IHF are binding sites for proteins described in the text. R sites are bound by DnaA. I sites are additional DnaA-binding sites (with different sequences, labeled I1, I2, and I3), for DnaA only when the protein is complexed with ATP.

TABLE 25-3 Proteins Required to Initiate Replication at the *E. coli* Origin

Protein	M_r	Number of subunits	Function
DnaA protein	52,000	1	Recognizes *oriC* sequence; opens duplex at specific sites in origin
DnaB protein (helicase)	300,000	6^a	Unwinds DNA
DnaC protein	174,000	6^a	Required for DnaB binding at origin
HU	19,000	2	Histonelike protein; DNA-binding protein; stimulates initiation
FIS	22,500	2^a	DNA-binding protein; stimulates initiation
IHF	22,000	2	DNA-binding protein; stimulates initiation
Primase (DnaG protein)	60,000	1	Synthesizes RNA primers
Single-stranded DNA–binding protein (SSB)	75,600	4^a	Binds single-stranded DNA
DNA gyrase (DNA topoisomerase II)	400,000	4	Relieves torsional strain generated by DNA unwinding
Dam methylase	32,000	1	Methylates (5′)GATC sequences at *oriC*

FIGURE 25-10 Model for initiation of replication at the *E. coli* origin, *oriC*. DnaA protein molecules bind initially at the five specific R sites. Upon ATP binding, additional DnaA molecules bind at the I sites in the origin, forming a right-handed helical complex and drawing in more DnaA molecules that continue the helix into the DUE region (see Fig. 25-9). The DNA is wrapped around this complex. DnaA molecules bound at the R and I sites bind the DNA with an HTH doman (referring to a DNA binding motif called helix-turn-helix). The A═T-rich DUE region is denatured as a result of the strain imparted by the DnaA binding. Within the DUE, single-stranded DNA is bound by the ATPase domain of DnaA rather than by the HTH. Formation of the helical DnaA complex is facilitated by the proteins HU, IHF, and FIS. The detailed structural roles of these proteins are not known, but IHF may stabilize a transient DNA loop, as shown here. Hexamers of the DnaB protein bind to each strand, with the aid of DnaC protein. The DnaB helicase activity further unwinds the DNA in preparation for priming and DNA synthesis. [Information from J. P. Erzberger et al., *Nat. Struct. Mol. Biol.* 13:676, 2006.]

Loading of the DnaB helicase is the key step in replication initiation. As a replicative helicase, DnaB migrates along the single-stranded DNA in the 5′→3′ direction, unwinding the DNA as it travels. The DnaB helicases loaded onto the two DNA strands thus travel in opposite directions, creating two potential replication forks. All other proteins at the replication fork are linked directly or indirectly to DnaB. The DNA polymerase III holoenzyme is linked through its τ subunits; additional DnaB interactions are described below. As replication begins and the DNA strands are separated at the fork, many molecules of single-stranded DNA–binding protein (SSB) bind to and stabilize the separated strands, and DNA gyrase (DNA topoisomerase II) relieves the topological stress induced ahead of the fork by the unwinding reaction.

Initiation is the only phase of DNA replication that is known to be regulated, and it is regulated such that replication occurs only once in each cell cycle. The mechanism of regulation is not yet entirely understood, but genetic and biochemical studies have provided insights into several separate regulatory mechanisms.

Once DNA polymerase III has been loaded onto the DNA, along with the β subunits (signaling completion of the initiation phase), the protein Hda binds to the β subunits and interacts with DnaA to stimulate hydrolysis of its bound ATP. Hda is yet another AAA+ ATPase closely related to DnaA (its name is derived from *h*omologous to *DnaA*). This ATP hydrolysis leads to disassembly of the DnaA complex at the origin. Slow release of ADP by DnaA and rebinding of ATP cycles the protein between its inactive (with bound ADP) and active (with bound ATP) forms on a time scale of 20 to 40 minutes.

The timing of replication initiation is affected by DNA methylation and interactions with the bacterial plasma membrane. The *oriC* DNA is methylated by the Dam methylase (Table 25-3), which methylates the N^6 position of adenine within the palindromic sequence (5′)GATC. (Dam is not a biochemical expletive; it stands for *D*NA *a*denine *m*ethylation.) The *oriC* region of *E. coli* is highly enriched in GATC sequences—it has 11 in its 245 bp; the average frequency of GATC in the *E. coli* chromosome as a whole is 1 in 256 bp.

Immediately after replication, the DNA is hemimethylated: the parent strands have methylated *oriC* sequences but the newly synthesized strands do not. The hemimethylated *oriC* sequences are now sequestered by interaction with the plasma membrane (the mechanism is unknown) and by binding of the protein SeqA. After a time, *oriC* is released from the plasma membrane, SeqA dissociates, and the DNA must be fully methylated by Dam methylase before it can again bind DnaA and initiate a new round of replication.

Elongation The elongation phase of replication includes two distinct but related operations: leading strand synthesis and lagging strand synthesis. Several enzymes at the replication fork are important to the synthesis of both strands. Parent DNA is first unwound by DNA helicases, and the resulting topological stress is relieved by topoisomerases. Each separated strand is then stabilized by SSB. From this point, synthesis of leading and lagging strands is sharply different.

Leading strand synthesis, the more straightforward of the two, begins with the synthesis by primase (DnaG protein) of a short (10 to 60 nucleotide) RNA primer at the replication origin. DnaG interacts with DnaB helicase to carry out this reaction, and the primer is synthesized in the direction opposite to that in which the DnaB helicase is moving. In effect, the DnaB helicase moves along the strand that becomes the lagging strand in DNA synthesis; however, the first primer laid down in the first DnaG-DnaB interaction serves to prime leading strand DNA synthesis in the opposite direction. Deoxyribonucleotides are added to this primer by a DNA polymerase III complex linked to the DnaB helicase tethered to the opposite DNA strand. Leading strand synthesis then proceeds continuously, keeping pace with the unwinding of DNA at the replication fork.

Lagging strand synthesis, as we have noted, is accomplished in short Okazaki fragments (**Fig. 25-11a**). First, an RNA primer is synthesized by primase, and, as in leading strand synthesis, DNA polymerase III binds to the RNA primer and adds deoxyribonucleotides (Fig. 25-11b). On this level, the synthesis of each Okazaki fragment seems straightforward, but the details are quite complex. The complexity lies in the *coordination* of leading and lagging strand synthesis. Both strands are produced by a *single* asymmetric DNA polymerase III dimer; this is accomplished by looping the DNA of the lagging strand as shown in **Figure 25-12**, bringing together the two points of polymerization.

The synthesis of Okazaki fragments on the lagging strand entails some elegant enzymatic choreography.

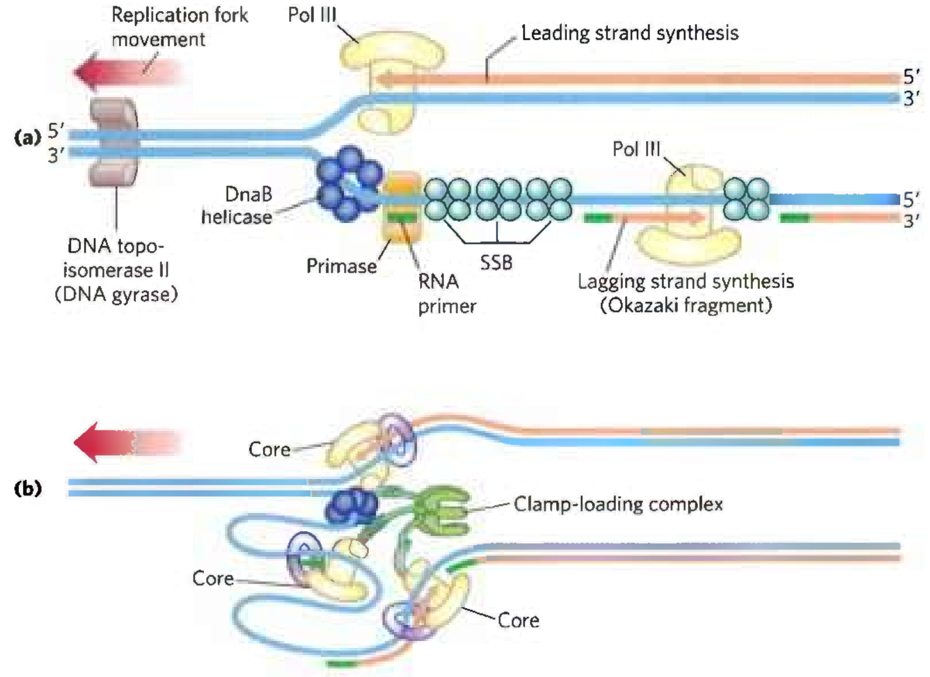

FIGURE 25-11 Synthesis of Okazaki fragments. (a) At intervals, primase synthesizes an RNA primer for a new Okazaki fragment. If we consider the two template strands as lying side by side, lagging strand synthesis formally proceeds in the opposite direction from fork movement. Each primer is extended by DNA polymerase III. DNA synthesis continues until the fragment extends as far as the primer of the previously added Okazaki fragment. A new primer is synthesized near the replication fork to begin the process again. (b) In the replisome complex, DNA synthesis on the leading and lagging strands is tightly coordinated. Each DNA polymerase III holoenzyme has three sets of core subunits (yellow), linked together with a single clamp-loading complex, so one or two Okazaki fragments can be synthesized simultaneously, along with the leading strand.

Continuous synthesis on the leading strand proceeds as DNA is unwound by the DnaB helicase.

Okazaki fragment synthesis nears completion.

Primase binds to DnaB, synthesizes a new primer, then dissociates.

A new β clamp is loaded onto the new template primer by the clamp loader.

Synthesis of a new Okazaki fragment is completed on the lagging strand.

Lagging strand core subunits are transferred to the new template primer and its β clamp. The old β clamp is left behind.

The next β clamp is readied as Okazaki fragment synthesis is initiated.

FIGURE 25-12 DNA synthesis on the leading and lagging strands. Events at the replication fork are coordinated by a single DNA polymerase III dimer, in an integrated complex with DnaB helicase. This figure shows the replication process already underway; (a) through (e) are discussed in the text. Only two sets of polymerase core subunits rather than three are shown, to more clearly illustrate the cycling on the lagging strand. The lagging strand is looped so that DNA synthesis proceeds steadily on both the leading and lagging strand templates at the same time. Red arrows indicate the 3′ end of the two new strands and the direction of DNA synthesis. An Okazaki fragment is being synthesized on the lagging strand. The subunit colors and the functions of the clamp-loading complex are explained in Figure 25-13.

DNA polymerase III uses one set of its core subunits (the core polymerase) to synthesize the leading strand continuously, while the other two sets of core subunits cycle from one Okazaki fragment to the next on the looped lagging strand. In vitro, a DNA polymerase III holoenzyme with only two sets of core subunits can synthesize both leading and lagging strands. However, a third set of core subunits increases the efficiency of lagging strand synthesis as well as the processivity of the overall replisome.

DnaB helicase, bound in front of DNA polymerase III, unwinds the DNA at the replication fork (Fig. 25-12a) as it travels along the lagging strand template in the 5′→3′ direction. DnaG primase occasionally associates with DnaB helicase and synthesizes a short RNA primer (Fig. 25-12b). A new β sliding clamp is then positioned at the primer by the clamp-loading complex of DNA polymerase III (Fig. 25-12c). When synthesis of an Okazaki fragment has been completed, replication halts, and the core subunits of DNA polymerase III dissociate from their

TABLE 25-4 Proteins of the *E. coli* Replisome

DNA polymerase III	1,065,400	17	New strand elongation
DNA polymerase I	103,000	1	Filling of gaps; excision of primers
DNA ligase	74,000	1	Ligation
DNA gyrase (DNA topoisomerase II)	400,000	4	Supercoiling

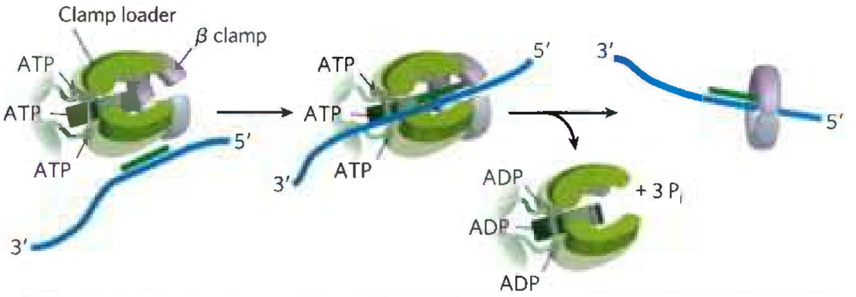

FIGURE 25-13 The DNA polymerase III clamp loader. The five subunits of the clamp-loading (γ) complex are the δ and δ' subunits and the amino-terminal domain of each of the three τ subunits (see Fig. 25-8). The complex binds to three molecules of ATP and to a dimeric β clamp. This binding forces the β clamp open at one of its two subunit interfaces. Hydrolysis of the bound ATP allows the β clamp to close again around the DNA.

β sliding clamp (and from the completed Okazaki fragment) and associate with the new clamp (Fig. 25-12d, e). This initiates synthesis of a new Okazaki fragment. Two sets of core subunits may be engaged in the synthesis of two different Okazaki fragments at the same time. The proteins acting at the replication fork are summarized in **Table 25-4**.

The clamp-loading complex of DNA polymerase III, consisting of parts of the three τ subunits along with the δ and δ' subunits, is also an AAA+ ATPase. This complex binds to ATP and to the new β sliding clamp. The binding imparts strain on the dimeric clamp, opening up the ring at one subunit interface (**Fig. 25-13**). The newly primed lagging strand is slipped into the ring through the resulting break. The clamp loader then hydrolyzes ATP, releasing the β sliding clamp and allowing it to close around the DNA.

The replisome promotes rapid DNA synthesis, adding ~1,000 to 2,000 nucleotides to each strand (leading and lagging). Once an Okazaki fragment has been completed, its RNA primer is removed by DNA polymerase I or RNase H1 and replaced with DNA by the polymerase; the remaining nick is sealed by DNA ligase (**Fig. 25-14**).

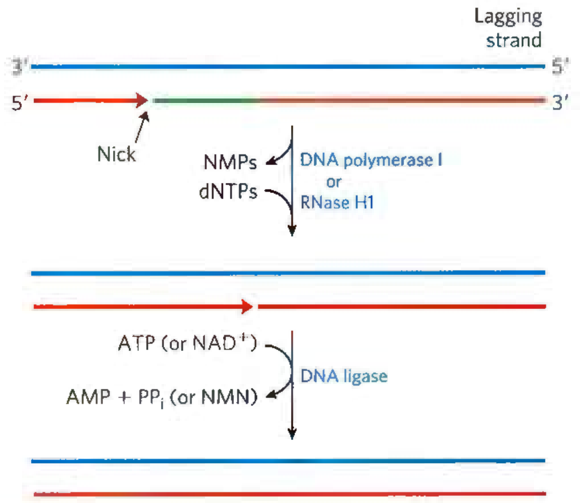

FIGURE 25-14 Final steps in the synthesis of lagging strand segments. RNA primers in the lagging strand are removed by the 5′→3′ exonuclease activity of DNA polymerase I or RNase H1, and then replaced with DNA by DNA polymerase I. The remaining nick is sealed by DNA ligase. The role of ATP or NAD$^+$ is shown in Figure 25-15.

DNA ligase catalyzes the formation of a phosphodiester bond between a 3′ hydroxyl at the end of one DNA strand and a 5′ phosphate at the end of another strand. The phosphate must be activated by adenylylation. DNA ligases isolated from viruses and eukaryotes use ATP for this purpose. DNA ligases from bacteria are unusual in that many use NAD$^+$—a cofactor that usually functions in hydride transfer reactions (see Fig. 13-24)—as the source of the AMP activating group (**Fig. 25-15**). DNA ligase is another enzyme of DNA metabolism that has become an important reagent in recombinant DNA experiments (see Fig. 9-1).

FIGURE 25-15 **Mechanism of the DNA ligase reaction.** In each of the three steps, one phosphodiester bond is formed at the expense of another. Steps ① and ② lead to activation of the 5′ phosphate in the nick. An AMP group is transferred first to a Lys residue on the enzyme and then to the 5′ phosphate in the nick. In step ③, the 3′-hydroxyl group attacks this phosphate and displaces AMP, producing a phosphodiester bond to seal the nick. In the *E. coli* DNA ligase reaction, AMP is derived from NAD^+. The DNA ligases isolated from some viral and eukaryotic sources use ATP rather than NAD^+, and they release pyrophosphate rather than nicotinamide mononucleotide (NMN) in step ①.

containing multiple copies of a 20 bp sequence called Ter (**Fig. 25-16**). The Ter sequences are arranged on the chromosome to create a trap that a replication fork can enter but cannot leave. The Ter sequences function as binding sites for the protein Tus (terminus utilization substance). The Tus-Ter complex can arrest a replication fork from only one direction. Only one Tus-Ter complex functions per replication cycle—the complex first encountered by either replication fork. Given that opposing replication forks generally halt when they collide, Ter sequences would not seem to be essential, but they may prevent overreplication by one fork in the event that the other is delayed or halted by an encounter with DNA damage or some other obstacle.

FIGURE 25-16 **Termination of chromosome replication in *E. coli*.** The Ter sequences (*TerA* through *TerJ*) are positioned on the chromosome in two clusters with opposite orientations. The overall Ter region encompasses about 9% of the circular chromosome.

So, when either replication fork encounters a functional Tus-Ter complex, it halts; the other fork halts when it meets the first (arrested) fork. The final few hundred base pairs of DNA between these large protein complexes are then replicated (by an as yet unknown mechanism), completing two topologically interlinked (catenated) circular chromosomes (**Fig. 25-17**). DNA circles linked in this way are known as **catenanes**. Separation of the catenated circles in *E. coli* requires topoisomerase IV (a type II topoisomerase). The separated chromosomes then segregate into daughter cells at cell division. The terminal phase of replication of other circular chromosomes, including many of the DNA viruses that infect eukaryotic cells, is similar.

Replication in Eukaryotic Cells Is Similar but More Complex

The DNA molecules in eukaryotic cells are considerably larger than those in bacteria and are organized into

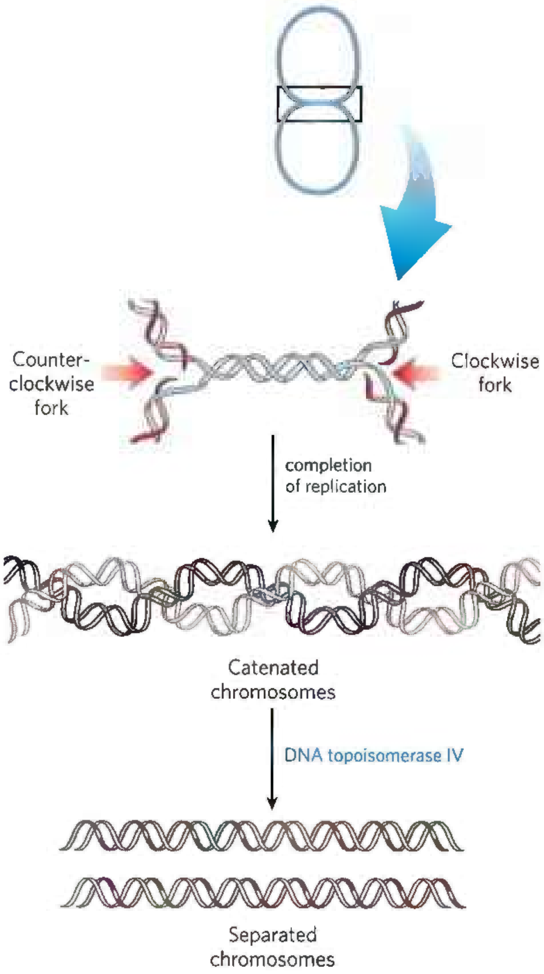

FIGURE 25-17 Role of topoisomerases in replication termination. Replication of the DNA separating opposing replication forks leaves the completed chromosomes joined as catenanes, or topologically interlinked circles. The circles are not covalently linked, but because they are interwound and each is covalently closed, they cannot be separated—except by the action of topoisomerases. In *E. coli*, a type II topoisomerase known as DNA topoisomerase IV plays the primary role in separating catenated chromosomes, transiently breaking both DNA strands of one chromosome and allowing the other chromosome to pass through the break.

complex nucleoprotein structures (chromatin; p. 898). The essential features of DNA replication are the same in eukaryotes and bacteria, and many of the protein complexes are functionally and structurally conserved. However, eukaryotic replication is regulated and coordinated with the cell cycle, and must function within the complexities of chromatin structure.

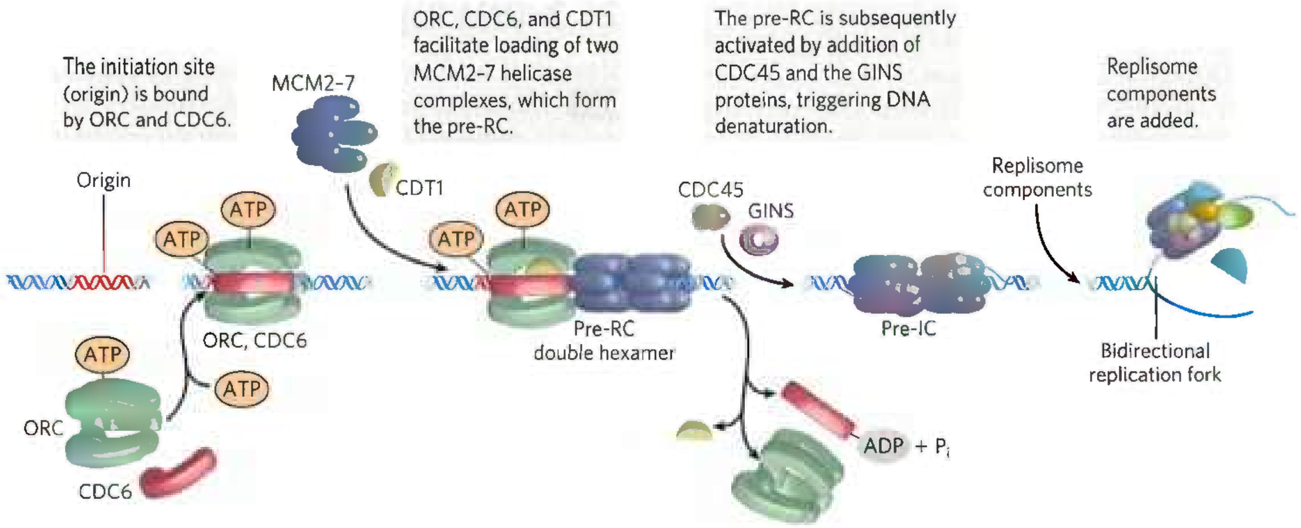
Origins of replication have a well-characterized structure in some lower eukaryotes, but they are much less defined in higher eukaryotes. In both cases, replication begins in short nucleosome-free regions. Yeast (*S. cerevisiae*) has about 400 defined replication origins called autonomously replicating sequences (ARSs), or **replicators**. Yeast replicators span ~150 bp and contain several essential, conserved sequences. There are about 30,000 to 50,000 replication origins in human chromosomes. The replication origins of vertebrates in general may be defined by some aspect of DNA secondary structure, as yet unknown.

Regulation ensures that all cellular DNA is replicated once per cell cycle. Much of this regulation involves proteins called cyclins and the cyclin-dependent kinases (CDKs) with which they form complexes (see Section 12.8). The cyclins are rapidly destroyed by ubiquitin-dependent proteolysis at the end of the M phase (mitosis), and the absence of cyclins allows the establishment of **prereplicative complexes (pre-RCs)** on replication initiation sites. In rapidly growing cells, the pre-RC forms at the end of M phase. In slow-growing cells, it does not form until the end of G1. Formation of the pre-RC renders the cell competent for replication, an event sometimes called **licensing**.

As in bacteria, the key event in the initiation of replication in all eukaryotes is the loading of the replicative helicase, a heterohexameric complex of **minichromosome maintenance (MCM) proteins** (MCM2 to MCM7). The ring-shaped MCM2–7 helicase functions in some ways like the bacterial DnaB helicase, although it translocates 3′→5′ along the leading strand template. It is loaded onto the DNA in steps (**Fig. 25-18**). The origin is recognized and bound first by another six-protein complex, called **ORC (origin recognition complex)**, followed by the protein CDC6 (cell division cycle), which recruits CDT1 (CDC10-dependent transcript 1). Together, they facilitate the loading of two inactive MCM2–7 complexes (the pre-RC). The ORC-CDC6 complex and CTD1 dissociate, leaving behind the pre-RC. ORC has five AAA+ ATPase domains among its subunits and is functionally analogous to the bacterial DnaA. The yeast CDC6 is yet another AAA+ ATPase that forms a complex with the ORC subunits. Following pre-RC formation, another set of proteins, CDC45 and the GINS, bind to and activate the MCM2–7 helicase, triggering DNA denaturation. (GINS refers to the first letters of the numbers 5-1-2-3 in Japanese, *go-ichi-ni-san*, providing a somewhat cryptic callout to the four protein subunits of the complex: SLD5, PSF1, PSF2, and PSF3.) The replication proteins then bind to form a replisome, and bidirectional replication begins.

Commitment to replication requires the synthesis and activity of S-phase cyclin-CDK complexes (such as the cyclin E–CDK2 complex; see Fig. 12-36) and CDC7-DBF4. Both types of complexes help to activate replication by binding to and phosphorylating several subunits of the pre-RC. Other cyclins and CDKs function to inhibit the formation of more pre-RC complexes once replication has been initiated. For example, CDK2 binds to cyclin A as cyclin E levels decline during S phase, inhibiting CDK2 and preventing the licensing of additional pre-RC complexes.

The rate of movement of the replication fork in eukaryotes (~50 nucleotides/s) is only one-twentieth that observed in *E. coli*. At this rate, replication of an average



The initiation site (origin) is bound by ORC and CDC6.

ORC, CDC6, and CDT1 facilitate loading of two MCM2-7 helicase complexes, which form the pre-RC.

The pre-RC is subsequently activated by addition of CDC45 and the GINS proteins, triggering DNA denaturation.

Replisome components are added.

FIGURE 25-18 Assembly of a prereplicative complex at a eukaryotic replication origin. The initiation site (origin) is bound by ORC, CDC6, and CDT1. These proteins, many of them AAA+ ATPases, promote loading of two MCM2–7 helicase complexes, in a reaction analogous to the loading of the bacterial DnaB helicase by DnaC protein. The two loaded but inactive MCM2–7 complexes comprise the prereplicative complex, or pre-RC. The pre-RC is subsequently activated by addition of CDC45 and the GINS proteins, followed by addition of the replisome components. [Information from M. W. Parker et al., *Crit. Rev. Biochem. Mol. Biol.* 52:107, 2017.]

human chromosome proceeding from a single origin would take more than 500 hours, making the requirement for many origins evident.

Like bacteria, eukaryotes have several types of DNA polymerases. Some have been linked to particular functions, such as the replication of mitochondrial DNA. The replication of nuclear chromosomes primarily involves three multisubunit DNA polymerases. The highly processive **DNA polymerase ε** synthesizes the leading strand, and **DNA polymerase δ** synthesizes the lagging strand. Both enzymes have 3′→5′ proofreading exonuclease activities. **DNA polymerase α**, a DNA polymerase/primase, synthesizes RNA primers and also extends them by about 10 nucleotides of DNA to initiate synthesis of each Okazaki fragment on the lagging strand. One subunit of DNA polymerase α has a primase activity, and the largest subunit (M_r ~180,000) contains the polymerization activity. However, this polymerase has no proofreading 3′→5′ exonuclease activity, making it unsuitable for high-fidelity DNA replication.

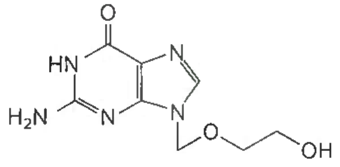
DNA polymerases ε and δ are associated with and stimulated by proliferating cell nuclear antigen (PCNA; M_r 29,000), a protein found in large amounts in the nuclei of proliferating cells. The three-dimensional structure of PCNA is remarkably similar to that of the β subunit of *E. coli* DNA polymerase III (Fig. 25-8b), although primary sequence homology is not evident. PCNA has a function analogous to that of the β subunit, forming a circular clamp that enhances the processivity of the two polymerases.

Two other protein complexes also function in eukaryotic DNA replication. RPA (replication protein A) is a single-stranded DNA–binding protein, equivalent in function to the *E. coli* SSB protein. RFC (replication factor C) is a clamp loader for PCNA and facilitates the assembly of active replication complexes. The subunits of the RFC complex have significant sequence similarity to the subunits of the bacterial clamp-loading (γ) complex.

Termination of replication on linear eukaryotic chromosomes occurs when replication forks operating from nearby origins converge. As in bacteria, there are successive steps of final replication, replisome dissociation, and decatenation of the DNA products. All of the steps are mediated by additional protein complexes, with some parts of the process still undefined.

Viral DNA Polymerases Provide Targets for Antiviral Therapy

Many DNA viruses encode their own DNA polymerases, and some of these have become targets for pharmaceuticals. For example, the DNA polymerase of the herpes simplex virus is inhibited by acyclovir, a compound developed by Gertrude Elion and George Hitchings (p. 836). Acyclovir consists of guanine attached to an incomplete ribose ring.



Acyclovir

It is phosphorylated by a virally encoded thymidine kinase; acyclovir binds to this viral enzyme with an affinity 200-fold greater than its binding to the cellular thymidine kinase. This ensures that phosphorylation occurs mainly in virus-infected cells. Cellular kinases convert the resulting acyclo-GMP to acyclo-GTP, which is both an inhibitor and a substrate of DNA polymerases; acyclo-GTP competitively inhibits the herpes DNA polymerase more strongly than cellular DNA polymerases. Because it lacks a 3′ hydroxyl, acyclo-GTP also acts as a chain terminator when incorporated into DNA. Thus viral replication is inhibited at several steps. ■

SUMMARY 25.1 *DNA Replication*

- Replication of DNA follows a set of universal rules. Replication is semiconservative, each strand acting as template for a new daughter strand. It is carried out in three identifiable phases: initiation, elongation, and termination. The process starts at a single origin in bacteria and usually proceeds bidirectionally. DNA is synthesized in the 5′→3′ direction by DNA polymerases. At the replication fork, the leading strand is synthesized continuously in the same direction as replication fork movement; the lagging strand is synthesized discontinuously as Okazaki fragments, which are subsequently ligated.
- Nucleases are enzymes that degrade DNA. Endonucleases cleave within a DNA polymer; exonucleases degrade DNA from the end of one strand (either 5′→3′ or 3′→5′).
- DNA polymerases are complex enzymes that synthesize DNA, and often possess additional activities, including exonuclease functions.
- DNA is replicated with very high fidelity. Accuracy is maintained by (1) base selection by the polymerase, (2) a 3′→5′ proofreading exonuclease activity that is part of many DNA polymerases, and (3) specific repair systems for mismatches left behind after replication.
- Most cells have several DNA polymerases. In *E. coli*, DNA polymerase III is the primary replication enzyme. DNA polymerase I is responsible for special functions during replication, recombination, and repair.
- Replication requires an array of enzymes and protein factors in addition to DNA polymerases. Many of these proteins belong to the AAA+ ATPase family.
- Replication initiation occurs when replicative helicases are loaded onto replication origins in stepwise fashion. Elongation is achieved by an active replisome—a supramolecular complex of nucleic acids and many proteins, including polymerases. Termination occurs when replisomes proceeding in opposite directions converge. It requires decatenation of the replication products when replication is complete.
- The major replicative DNA polymerases in eukaryotes are DNA polymerases ε and δ. DNA polymerase α synthesizes primers.
- Viral DNA replication is a drug target.

25.2 DNA Repair

Most cells have only one or two sets of genomic DNA. P1 Damaged proteins and RNA molecules can be quickly replaced by using information encoded in the DNA, but DNA molecules themselves are irreplaceable. Maintaining the integrity of the information in DNA is a cellular imperative, supported by an elaborate set of DNA repair systems. DNA can become damaged by a variety of processes, some spontaneous, others catalyzed by environmental agents (Chapter 8). Replication itself can very occasionally damage the information content in DNA when polymerase errors create mismatched base pairs (such as G paired with T).

The chemistry of DNA damage is diverse and complex. The cellular response to this damage includes enzymatic systems that catalyze some of the most interesting chemical transformations in DNA metabolism. We first examine the effects of alterations in DNA sequence and then consider specific repair systems.

Mutations Are Linked to Cancer

The best way to illustrate the importance of DNA repair is to consider the effects of *unrepaired* DNA damage (a lesion). P3 The most serious outcome is a change in the base sequence of the DNA, which, if replicated and transmitted to future generations of cells, becomes permanent. A permanent change in the nucleotide sequence of DNA is called a **mutation**. Mutations can involve the replacement of one base pair with another (substitution mutation) or the addition or deletion of one or more base pairs (insertion or deletion mutations). If the mutation affects nonessential DNA or if it has a negligible effect on the function of a gene, it is known as a **silent mutation**. P1 P3 Rarely, a mutation confers some biological advantage. Most nonsilent mutations, however, are neutral or deleterious.

In mammals there is a strong correlation between the accumulation of mutations and cancer. A simple test developed by Bruce Ames in the 1970s measures the potential of a given chemical compound to promote certain easily detected mutations in a specialized bacterial strain (**Fig. 25-19**). Few of the chemicals that we encounter in daily life score as mutagens in this test. However, of the compounds known to be carcinogenic from extensive animal trials, more than 90% are also found to be mutagenic in the Ames test. Because of this strong correlation between mutagenesis and carcinogenesis, the Ames test for bacterial mutagens is still widely used as a rapid and inexpensive screen for potential human carcinogens.

The genomic DNA in a typical mammalian cell accumulates many thousands of lesions during a 24-hour period. However, as a result of DNA repair, fewer than 1 in 1,000 become a mutation. DNA is a relatively stable molecule, but in the absence of repair systems, the cumulative effect of many infrequent but damaging reactions would make life impossible. ■

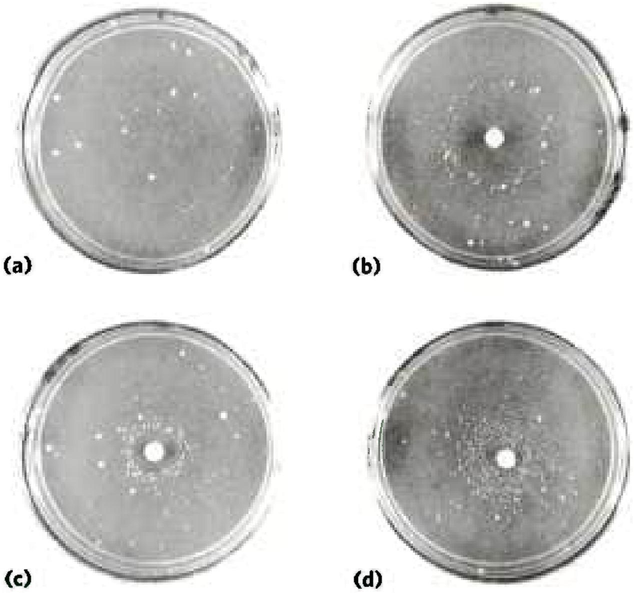


FIGURE 25-19 Ames test for carcinogens, based on their mutagenicity. A strain of *Salmonella typhimurium* having a mutation that inactivates an enzyme of the histidine biosynthetic pathway is plated on a histidine-free medium. Few cells grow. (a) The few small colonies of *S. typhimurium* that do grow on a histidine-free medium carry spontaneous mutations that permit the histidine biosynthetic pathway to operate. Three identical nutrient plates (b), (c), and (d) have been inoculated with an equal number of cells. Each plate then receives a disk of filter paper containing progressively lower concentrations of a mutagen. The mutagen greatly increases the rate of back-mutation and hence the number of colonies. The clear areas around the filter paper indicate where the concentration of mutagen is so high that it is lethal to the cells. As the mutagen diffuses away from the filter paper, it is diluted to sublethal concentrations that promote back-mutation. Mutagens can be compared on the basis of their effect on mutation rate. Because many compounds undergo a variety of chemical transformations after entering cells, compounds are sometimes tested for mutagenicity after first incubating them with a liver extract. Some substances have been found to be mutagenic only after this treatment. [Bruce N. Ames, University of California, Berkeley, Department of Biochemistry and Molecular Biology.]

TABLE 25-5 Types of DNA Repair Systems in *E. coli*

Enzymes/proteins	Type of damage
Mismatch repair	
Dam methylase	Mismatches
MutH, MutL, MutS proteins	
DNA helicase II	
SSB	
DNA polymerase III	
Exonuclease I	
Exonuclease VII	
RecJ nuclease	
Exonuclease X	
DNA ligase	
Base-excision repair	
DNA glycosylases	Abnormal bases (uracil, hypoxanthine, xanthine); alkylated bases; in some other organisms, pyrimidine dimers
AP endonucleases

DNA photolyases	Pyrimidine dimers
O^6-Methylguanine-DNA methyltransferase	O^6-Methylguanine
AlkB protein	1-Methylguanine, 3-methylcytosine

All Cells Have Multiple DNA Repair Systems

The number and diversity of repair systems reflect both the importance of DNA repair to cell survival and the diverse sources of DNA damage (**Table 25-5**). Some common types of lesions, such as pyrimidine dimers (see Fig. 8-30), can be repaired by several distinct systems. Nearly 200 genes in the human genome encode proteins dedicated to DNA repair. In many cases, the loss of function of one of these proteins results in genomic instability and an increased occurrence of oncogenesis (**Box 25-1**).

P2 Many DNA repair processes also seem to be extraordinarily inefficient energetically—an exception to the pattern observed in the vast majority of metabolic pathways, where every ATP is generally accounted for and used optimally. When the integrity of the genetic information is at stake, the amount of chemical energy invested in a repair process seems almost irrelevant.

Accurate DNA repair is possible largely because the DNA molecule consists of two complementary strands. Damaged DNA in one strand can be removed and replaced, without introducing mutations, by using the undamaged complementary strand as a template. We consider here the principal types of repair systems, beginning with those that repair the rare nucleotide mismatches that are left behind by replication.

Mismatch Repair Correction of the rare mismatches left after replication in *E. coli* improves the overall fidelity of replication by an additional factor of 10^2 to 10^3. The mismatches are nearly always corrected to reflect the information in the old (template) strand, which the repair system can distinguish from the newly synthesized strand by the presence of methyl group tags on the template DNA. The mismatch repair system of *E. coli* includes at least 10 protein components (Table 25-5) that function either in strand discrimination or in the repair process itself. The functions of many of these were first worked out by Paul Modrich and colleagues in the 1980s.

The strand discrimination mechanism has not been determined for most bacteria or eukaryotes, but it is well understood for *E. coli* and some closely related bacterial species. In these bacteria, strand discrimination is based on the action of Dam methylase, which, as you will recall, methylates DNA at the N^6 position of all adenines within (5′)GATC sequences. Immediately after passage of the replication fork, there is a short period (a few seconds or minutes) during which the template strand is methylated

BOX 25-1 MEDICINE

DNA Repair and Cancer

Human cancers develop when genes that regulate normal cell division (oncogenes and tumor suppressor genes; see Chapter 12) fail to function, are activated at the wrong time, or are altered. As a consequence, cells may grow out of control and form a tumor. The genes controlling cell division can be damaged by spontaneous mutation or overridden by the invasion of a tumor virus (Chapter 26). Not surprisingly, alterations in DNA repair genes that result in a higher rate of mutation can greatly increase an individual's susceptibility to cancer. Defects in the genes encoding the proteins involved in nucleotide-excision repair, mismatch repair, recombinational repair, and error-prone translesion DNA synthesis have all been linked to human cancers. Clearly, DNA repair can be a matter of life and death.

Nucleotide-excision repair requires a larger number of proteins in humans than in bacteria, although the overall pathways are very similar. Genetic defects that inactivate nucleotide-excision repair have been associated with several genetic diseases, the best-studied of which is xeroderma pigmentosum (XP). Because nucleotide-excision repair is the sole repair pathway for pyrimidine dimers in humans, people with XP are extremely sensitive to light and readily develop sunlight-induced skin cancers. Most people with XP also have neurological abnormalities, presumably because of their inability to repair certain lesions caused by the high rate of oxidative metabolism in neurons. Defects in the genes encoding any of at least seven different protein components of the nucleotide-excision repair system can result in XP, giving rise to seven different genetic groups, denoted XPA to XPG. Note that XPC and XPE are parts of complexes that recognize damaged DNA, whereas XPA, XPB, XPD, XPF, and XPG are all components of a much larger multisubunit complex that represents the human excinuclease depicted in Figure 25-24. These proteins are involved in making the DNA incisions and removing the 29mer segment of DNA.

Most microorganisms have redundant pathways for the repair of cyclobutane pyrimidine dimers — making use of DNA photolyases and sometimes base-excision repair as alternatives to nucleotide-excision repair — but humans and other placental mammals do not. This lack of a backup for nucleotide-excision repair for removing pyrimidine dimers has led to speculation that early mammals were small, furry, nocturnal animals with little need to repair UV damage. However, mammals do have a pathway for the translesion bypass of cyclobutane pyrimidine dimers, which involves DNA polymerase η. This enzyme preferentially inserts two A residues opposite a T–T pyrimidine dimer, minimizing mutations. People with a genetic condition in which DNA polymerase η function is missing exhibit an XP-like illness known as XP-variant, or XP-V. Clinical manifestations of XP-V are similar to those of the classic XP diseases, although mutation levels are higher in XP-V when cells are exposed to UV light. Apparently, the nucleotide-excision repair system works in concert with DNA polymerase η in normal human cells, repairing and/or bypassing pyrimidine dimers as needed to keep cell growth and DNA replication going. Exposure to UV light introduces a heavy load of pyrimidine dimers, and some must be bypassed by translesion synthesis to keep replication on track. When one system is missing, it is partly compensated for by the other. A loss of DNA polymerase η activity leads to stalled replication forks and bypass of UV lesions by different, more mutagenic, translesion synthesis (TLS) polymerases. As when other DNA repair systems are absent, the resulting increase in mutations often leads to cancer.

One of the most common inherited cancer-susceptibility syndromes is hereditary nonpolyposis colon cancer (HNPCC). This syndrome has been traced to defects in mismatch repair. Human and other eukaryotic cells have several proteins analogous to the bacterial MutL and MutS proteins (see Fig. 25-21). Defects in at least five different mismatch repair genes can give rise to HNPCC. The most prevalent are defects in the *hMLH1* (*h*uman *M*ut*L* *h*omolog *1*) and *hMSH2* (*h*uman *M*ut*S* *h*omolog *2*) genes. In individuals with HNPCC, cancer generally develops at an early age, with colon cancers being most common.

Most human breast and ovarian cancer occurs in women with no known predisposition. However, about 10% of cases are associated with inherited defects in two genes, *BRCA1* and *BRCA2*. Human BRCA1 and BRCA2 are large proteins (1,834 and 3,418 amino acid residues, respectively) that interact with a wide range of other proteins involved in transcription, chromosome maintenance, DNA repair, and control of the cell cycle. BRCA2 has been implicated in the recombinational DNA repair of double-strand breaks. One of the key roles of BRCA2 is to load the human RecA homolog, called Rad51, onto DNA at the sites of double-strand breaks. BRCA1 has as yet imperfectly defined roles in the repair of double-strand breaks, transcription, and some other processes of DNA metabolism. Women with defects in either the *BRCA1* or *BRCA2* gene have a high (~70%) chance of developing breast cancer.

---

but the newly synthesized strand is not (**Fig. 25-20**). The transient unmethylated state of GATC sequences in the newly synthesized strand permits the new strand to be distinguished from the template strand. Replication mismatches in the vicinity of a hemimethylated GATC sequence are then repaired according to the information in the methylated parent (template) strand. If both strands are methylated at a GATC sequence, few mismatches are repaired; if neither strand is methylated, repair occurs but does not favor either strand. The methyl-directed mismatch repair system of *E. coli* efficiently repairs mismatches up to 1,000 bp from a hemimethylated GATC sequence.

How is the mismatch correction process directed by relatively distant GATC sequences? **Figure 25-21** illustrates one mechanism. MutS scans the DNA and forms a clamplike complex upon encountering a lesion. The complex binds to all mismatched base pairs (except C–C). MutL protein forms a complex with MutS protein, and the MutSL complex slides along the DNA to find a hemimethylated GATC sequence. MutH binds to MutL, and the MutSLH complex moves in either direction at random along the DNA. MutH has a site-specific endonuclease activity that is inactive until the complex encounters a hemimethylated GATC sequence. At this site, MutH catalyzes cleavage of the unmethylated strand on the 5′ side of the G in GATC, which marks the strand for repair. Further steps in the pathway depend on where the mismatch is located relative to this cleavage site (**Fig. 25-22**).

When the mismatch is on the 5′ side of the cleavage site (Fig. 25-22, right side), the unmethylated strand is unwound and degraded in the 3′→5′ direction from the

For a short period following replication, the template strand is methylated and the new strand is not.

After a few minutes, the new strand is methylated and the two strands can no longer be distinguished.

FIGURE 25-20 Methylation and mismatch repair. Methylation of DNA strands can serve to distinguish parent (template) strands from newly synthesized strands in *E. coli* DNA, a function that is critical to mismatch repair. The methylation occurs at the N^6 of adenines in (5′)GATC sequences. This sequence is a palindrome, present in opposite orientations on the two strands.

MutSL complex forms around the DNA at the mismatch and moves along the DNA to MutH bound at a hemimethylated GATC.

MutH cleaves the unmethylated strand on the 5′ side of G in the GATC sequence.

FIGURE 25-21 A model for the early steps of methyl-directed mismatch repair. Recognition of the sequence (5′)GATC and of the mismatch are specialized functions of the MutH and MutS proteins, respectively.

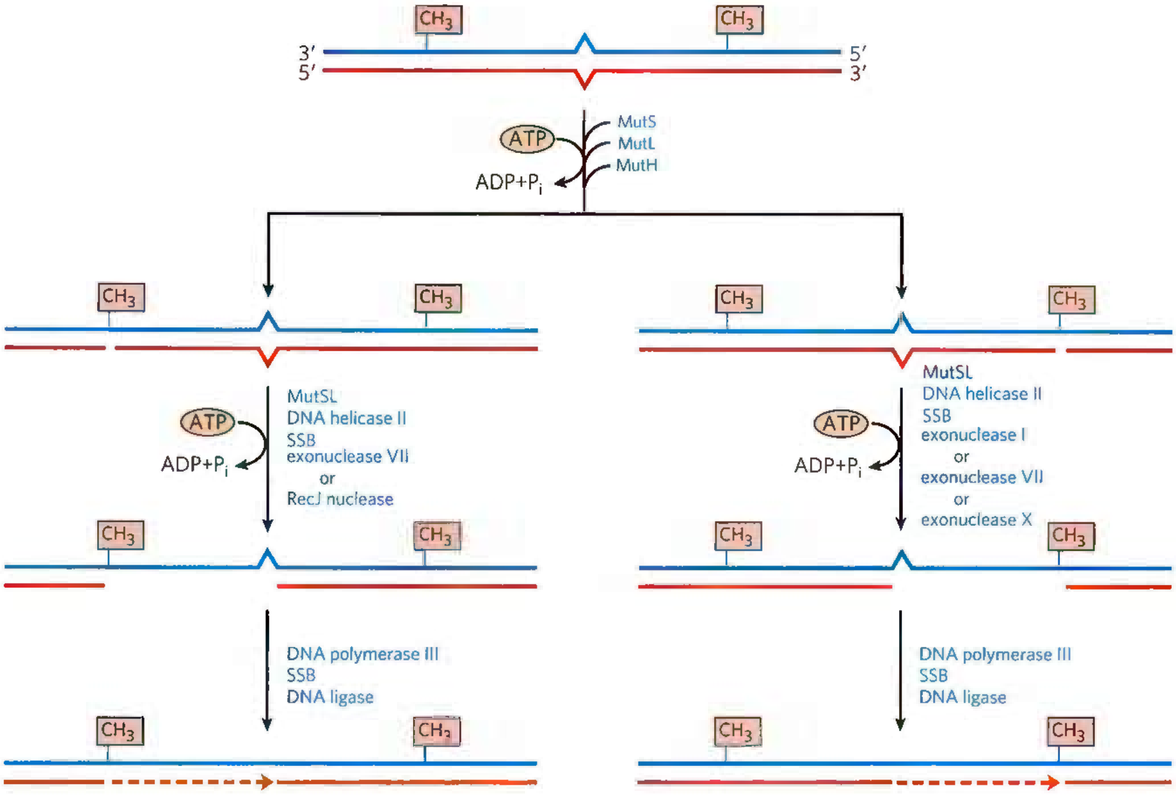

FIGURE 25-22 Completion of methyl-directed mismatch repair. The combined action of DNA helicase II, SSB, and one of four different exonucleases removes a segment of the new strand between the MutH cleavage site and a point just beyond the mismatch. The particular exonuclease depends on the location of the cleavage site relative to the mismatch, as shown by the alternative pathways here. The resulting gap is filled in (dashed line) by DNA polymerase III, and the nick is sealed by DNA ligase (not shown).

cleavage site through the mismatch, and this segment is replaced with new DNA. This process requires the combined action of DNA helicase II (also called UvrD helicase), SSB, exonuclease I or exonuclease X (both of which degrade strands of DNA in the 3′→5′ direction) or exonuclease VII (which degrades single-stranded DNA in either direction), DNA polymerase III, and DNA ligase. The pathway for repair of mismatches on the 3′ side of the cleavage site is similar (Fig. 25-22, left), except that the exonuclease is either exonuclease VII or RecJ nuclease (which degrades single-stranded DNA in the 5′→3′ direction).

P2 Mismatch repair is particularly costly for *E. coli* in terms of energy expended. The mismatch may occur 1,000 or more base pairs from the GATC sequence. The degradation and replacement of a strand segment of this length require an enormous investment in activated deoxynucleotide precursors to repair a *single* mismatched base. This again underscores the importance to the cell of genomic integrity.

Eukaryotic cells also have mismatch repair systems, with several proteins structurally and functionally analogous to the bacterial MutS and MutL (but not MutH) proteins. Alterations in human genes encoding proteins of this type produce some of the most common inherited cancer-susceptibility syndromes (see Box 25-1), further demonstrating the value to the organism of DNA repair systems. The main MutS homologs in most eukaryotes, from yeast to humans, are MSH2 (MutS homolog), MSH3, and MSH6. Heterodimers of MSH2 and MSH6 generally bind to single base-pair mismatches, and they bind less well to slightly longer mispaired loops. In many organisms, the longer mismatches (2 to 6 bp) may be bound instead by a heterodimer of MSH2 and MSH3, or are bound by both types of heterodimers in tandem. Homologs of MutL, predominantly a heterodimer of MLH1 (MutL homolog) and PMS1 (post-meiotic segregation), bind to and stabilize the MSH complexes. Many details of the subsequent events in eukaryotic mismatch repair remain to be worked out. In particular, we do not know how newly synthesized DNA strands are identified, although research reveals that this process does not involve GATC sequences.

Base-Excision Repair Every cell has a class of enzymes called **DNA glycosylases** that recognize particularly common DNA lesions (such as the products of cytosine and adenine deamination; see Fig. 8-29a) and remove the affected base by cleaving the *N*-glycosyl bond. The repair pathway is called **base-excision repair**, as the first step involves only the removal of the base rather than an entire nucleotide. The cleavage creates an apurinic or apyrimidinic site in the DNA, commonly referred to as an **AP site** or **abasic site**. Each DNA glycosylase is generally specific for one type of lesion.

Uracil DNA glycosylases, for example, found in most cells, specifically remove from DNA the uracil that results from spontaneous deamination of cytosine. Mutant cells that lack this enzyme have a high rate of G≡C to A=T mutations. This glycosylase does not remove uracil residues from RNA or thymine residues from DNA. The capacity to distinguish thymine from uracil, the product of cytosine deamination—necessary for the selective repair of the latter—may be one reason why DNA evolved to contain thymine instead of uracil (p. 280).

Most bacteria have just one type of uracil DNA glycosylase, whereas humans have at least four types, with different specificities—an indicator of the importance of removing uracil from DNA. The most abundant human uracil glycosylase, UNG, is associated with the replisome, where it eliminates the occasional U residue inserted in place of a T during replication. The deamination of C residues is 100-fold faster in single-stranded DNA than in double-stranded DNA, and humans have an enzyme, hSMUG1, that removes any U residues occurring in single-stranded DNA during replication or transcription. Two other human DNA glycosylases, TDG and MBD4, remove either U or T residues paired with G, which are generated by deamination of cytosine or 5-methylcytosine, respectively.

Other DNA glycosylases recognize and remove a variety of damaged bases, including formamidopyrimidine and 8-hydroxyguanine (both arising from purine oxidation), hypoxanthine (from adenine deamination), and alkylated bases such as 3-methyladenine and 7-methylguanine. Glycosylases that recognize other lesions, including pyrimidine dimers, have also been identified in some classes of organisms. Remember that AP sites also arise from slow, spontaneous hydrolysis of the *N*-glycosyl bonds in DNA (see Fig. 8-29b).

Once an AP site has been formed by a DNA glycosylase, another type of enzyme must repair it. The repair is *not* made by simply inserting a new base and re-forming the *N*-glycosyl bond. Instead, the deoxyribose 5′-phosphate left behind is removed and replaced with a new nucleotide. This process begins with one of the **AP endonucleases**, enzymes that cut the DNA strand containing the AP site. The position of the incision relative to the AP site (5′ or 3′ to the site) depends on the type of AP endonuclease. A segment of DNA including the AP site is then removed, DNA polymerase I replaces the DNA, and DNA ligase seals the remaining nick (**Fig. 25-23**). In eukaryotes, nucleotide replacement is carried out by specialized polymerases, as described below.

Nucleotide-Excision Repair DNA lesions that cause large distortions in the helical structure of DNA generally are repaired by the nucleotide-excision system, a repair pathway critical to the survival of all free-living organisms. In nucleotide-excision repair (**Fig. 25-24**),

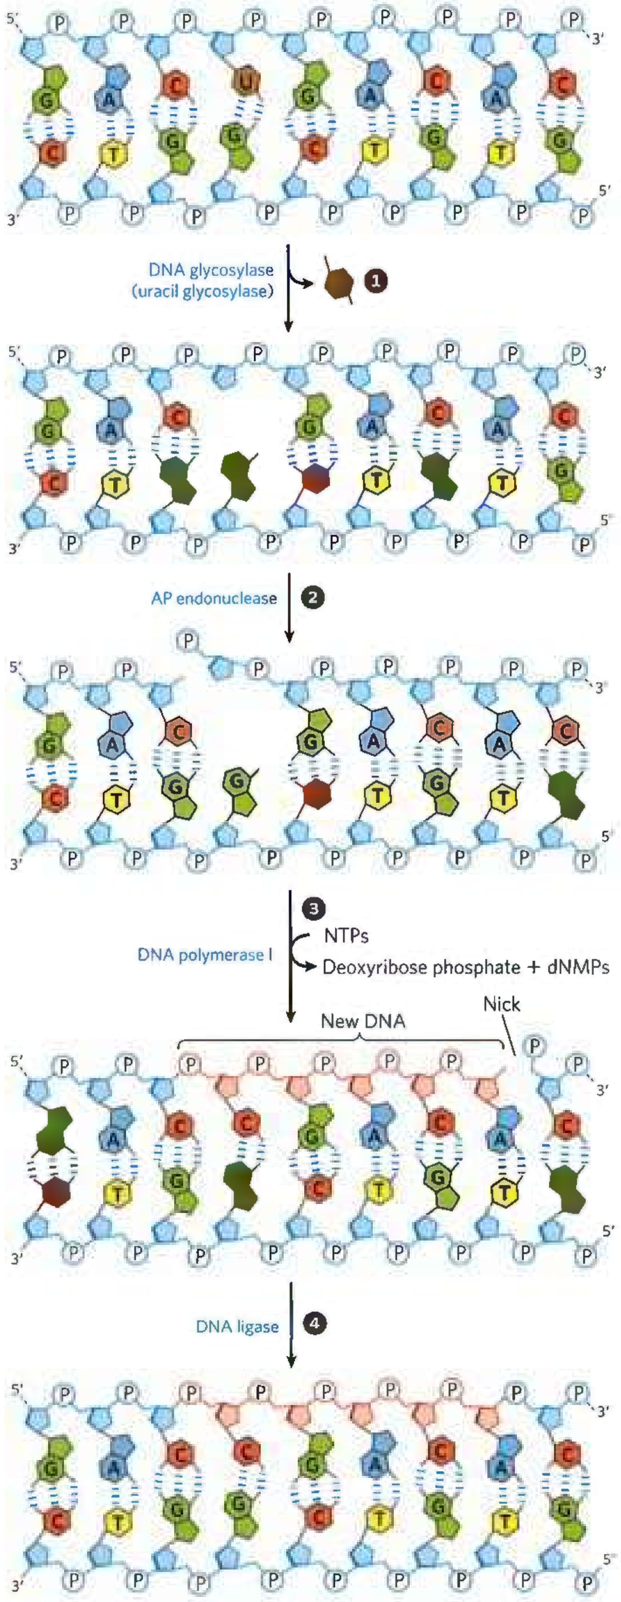

FIGURE 25-23 DNA repair by the base-excision repair pathway. ① A DNA glycosylase recognizes a damaged base (in this case, a uracil) and cleaves between the base and deoxyribose in the backbone. ② An AP endonuclease cleaves the phosphodiester backbone near the AP site. ③ DNA polymerase I initiates repair synthesis from the free 3′ hydroxyl at the nick, removing (with its 5′→3′ exonuclease activity) and replacing a portion of the damaged strand. ④ The nick remaining after DNA polymerase I has dissociated is sealed by DNA ligase.

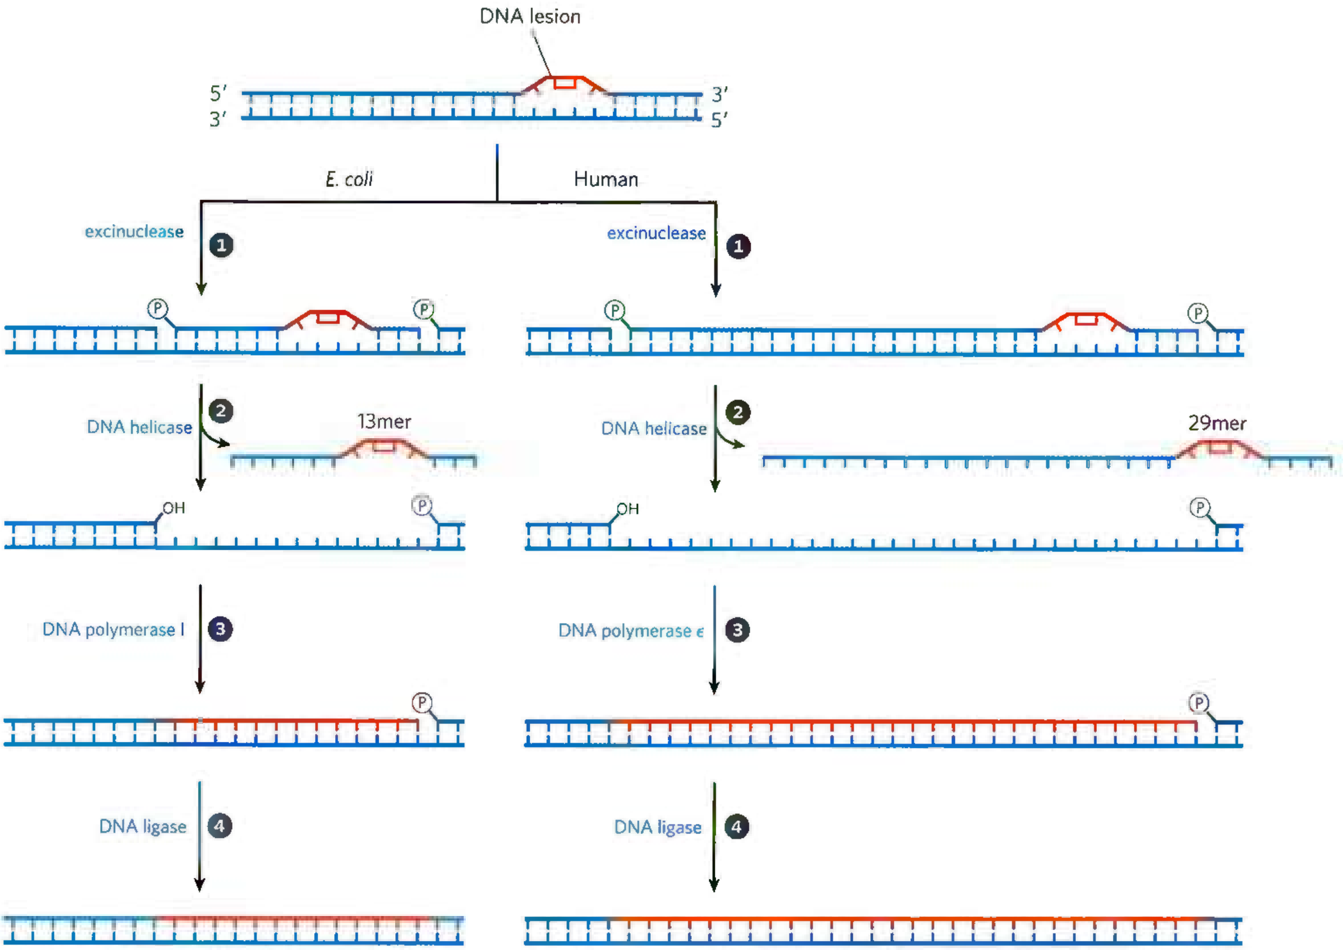

FIGURE 25-24 Nucleotide-excision repair in *E. coli* and humans. The general pathway of nucleotide-excision repair is similar in all organisms. ① An excinuclease binds to DNA at the site of a bulky lesion and cleaves the damaged DNA strand on either side of the lesion. ② The DNA segment — of 13 nucleotides (13mer) or 29 nucleotides (29mer) — is removed with the aid of a helicase. ③ The gap is filled in by DNA polymerase, and ④ the remaining nick is sealed with DNA ligase. [Information from a figure provided by Aziz Sancar.]

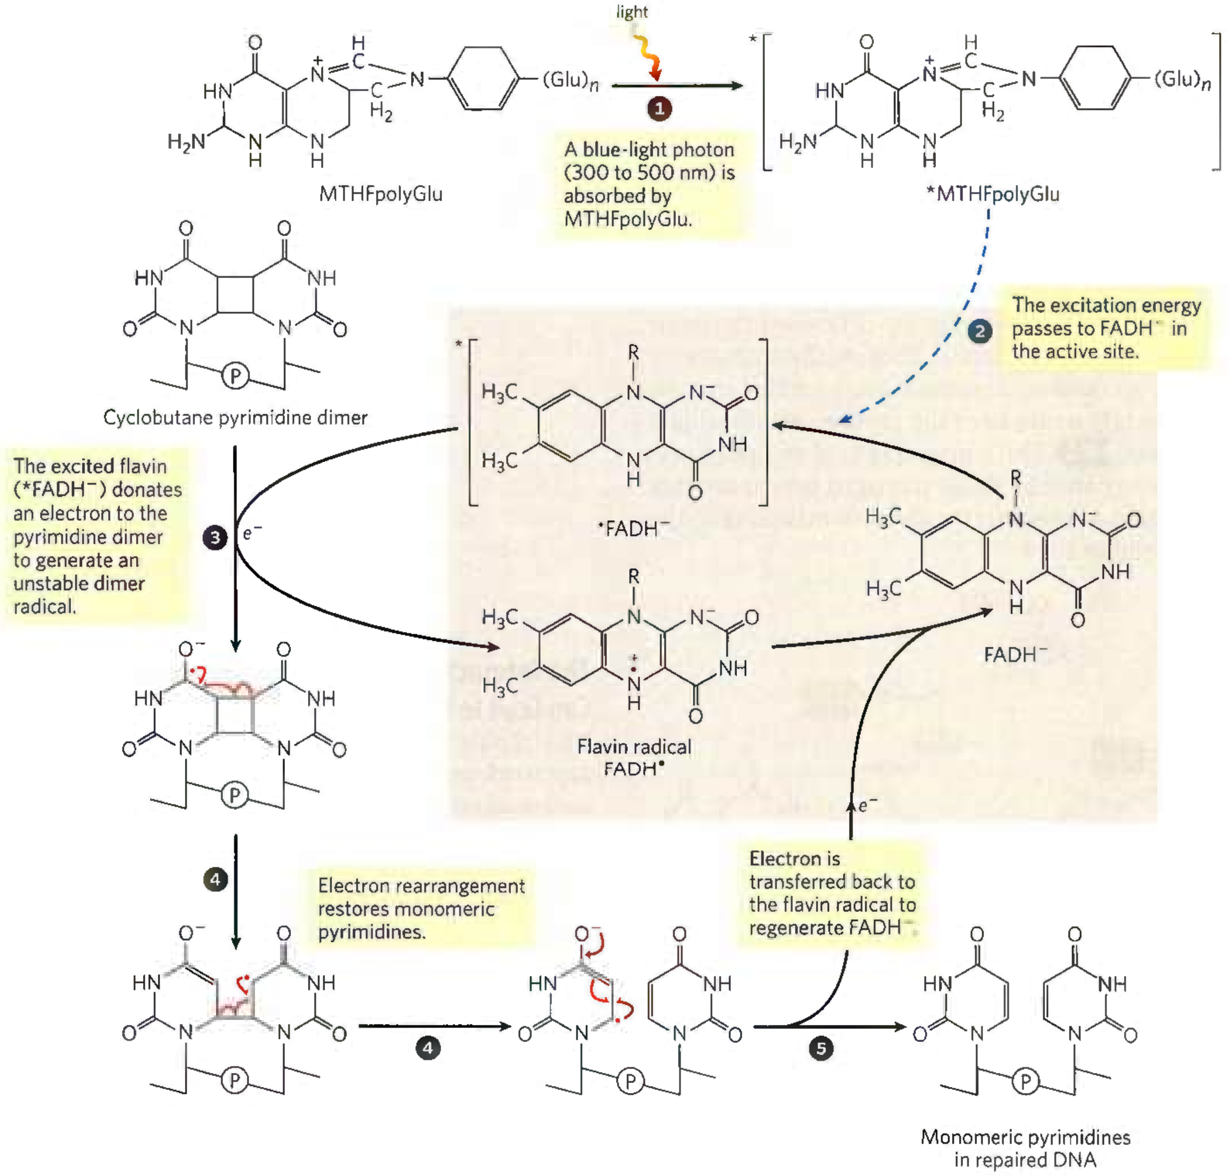
a multisubunit enzyme (excinuclease) hydrolyzes two phosphodiester bonds, one on either side of the distortion caused by the lesion. In *E. coli* and other bacteria, the enzyme system hydrolyzes the fifth phosphodiester bond on the 3′ side and the eighth phosphodiester bond on the 5′ side to generate a fragment of 12 to 13 nucleotides (depending on whether the lesion involves one or two bases). In humans and other eukaryotes, the enzyme system hydrolyzes the sixth phosphodiester bond on the 3′ side and the twenty-second phosphodiester bond on the 5′ side, producing a fragment of 27 to 29 nucleotides. Following the dual incision, the excised oligonucleotides are released from the duplex and the resulting gap is filled — by DNA polymerase I in *E. coli* and DNA polymerase ε in humans. DNA ligase seals the nick.

In *E. coli*, the key enzymatic complex is the ABC excinuclease, which has three protein components, UvrA (M_r 104,000), UvrB (M_r 78,000), and UvrC (M_r 68,000). The term "excinuclease" is used to describe the unique capacity of this enzyme complex to catalyze two specific endonucleolytic cleavages, distinguishing this activity from that of standard endonucleases. A dimeric UvrA protein (an ATPase) scans the DNA and binds to the site of a lesion. A UvrB protein can bind to UvrA either before or after an encounter with the lesion. At the lesion, the UvrA dimer dissociates, leaving a tight UvrB-DNA complex. UvrC protein then binds to UvrB, and UvrB makes an incision at the fifth phosphodiester bond on the 3′ side of the lesion. This is followed by a UvrC-mediated incision at the eighth phosphodiester bond on the 5′ side. The resulting fragment, consisting of 12 to 13 nucleotides, is removed by UvrD helicase. The short gap thus created is filled in by DNA polymerase I and DNA ligase. This pathway (Fig. 25-24, left) is a primary repair route for many types of lesions, including cyclobutane pyrimidine dimers, 6-4 photoproducts (see Fig. 8-30), and several other types of base adducts, including benzo[*a*]pyrene-guanine, which is formed in DNA by exposure to cigarette smoke. The nucleolytic activity of the ABC excinuclease is novel in the sense that two cuts are made in the DNA.

The mechanism of eukaryotic excinucleases is quite similar to that of the bacterial enzyme, although at least 16 polypeptides with no similarity to the *E. coli* excinuclease subunits are required for the dual incision. Some of the nucleotide-excision repair and base-excision repair in eukaryotes is closely tied to transcription (see Chapter 26). Genetic deficiencies in nucleotide-excision repair in humans give rise to a variety of serious diseases (see Box 25-1).

Direct Repair Several types of damage are repaired without removing a base or nucleotide. The best-characterized example is direct photoreactivation of cyclobutane pyrimidine dimers, a reaction promoted by **DNA photolyases**. Pyrimidine dimers result from a UV-induced reaction. Through a mechanism worked out by Aziz Sancar and colleagues, photolyases use energy derived from absorbed light to reverse the damage (**Fig. 25-25**). Photolyases generally contain two cofactors that serve as light-absorbing agents, or chromophores: in all organisms, one is $FADH_2$; in *E. coli* and yeast, the other is a folate. The reaction mechanism entails the generation of free radicals. DNA photolyases are not found in humans and other placental mammals.

Additional examples are seen in the repair of nucleotides with alkylation damage. The modified nucleotide O^6-methylguanine forms in the presence of alkylating agents and is a common and highly mutagenic lesion. It tends to pair with thymine rather than cytosine during replication, and therefore causes G≡C to A=T mutations (**Fig. 25-26**).



① A blue-light photon (300 to 500 nm) is absorbed by MTHFpolyGlu.

② The excitation energy passes to FADH⁻ in the active site.

③ The excited flavin (*FADH⁻) donates an electron to the pyrimidine dimer to generate an unstable dimer radical.

④ Electron rearrangement restores monomeric pyrimidines.

⑤ Electron is transferred back to the flavin radical to regenerate FADH⁻.

MECHANISM FIGURE 25-25 Repair of pyrimidine dimers with photolyase. Energy derived from absorbed light is used to reverse the photoreaction that caused the lesion. The two chromophores in *E. coli* photolyase (M_r 54,000), N^5,N^{10}-methenyltetrahydrofolylpolyglutamate (MTHFpolyGlu) and FADH⁻, perform complementary functions. MTHFpolyGlu functions as a photoantenna to absorb blue-light photons. The excitation energy passes to FADH⁻, and the excited flavin (*FADH⁻) donates an electron to the pyrimidine dimer, leading to the rearrangement as shown.

Direct repair of O^6-methylguanine is carried out by O^6-methylguanine-DNA methyltransferase, a protein that catalyzes transfer of the methyl group of O^6-methylguanine to one of its own Cys residues. This methyltransferase is not strictly an enzyme, because a single methyl transfer event permanently methylates the protein, inactivating it in this pathway. **P2** The consumption of an entire protein molecule to correct a single damaged base is another vivid illustration of the priority given to maintaining the integrity of cellular DNA.

A very different but equally direct mechanism is used to repair 1-methyladenine and 3-methylcytosine. The amino groups of A and C residues are sometimes methylated when the DNA is single-stranded, and the methylation directly affects proper base pairing. In *E. coli*, oxidative demethylation of these alkylated nucleotides is mediated by the AlkB protein, a member of the α-ketoglutarate-Fe^{2+}–dependent dioxygenase superfamily (**Fig. 25-27**). (See Box 4-2 for a description of proline hydroxylation, catalyzed by another member of this enzyme family.)

The Interaction of Replication Forks with DNA Damage Can Lead to Error-Prone Translesion DNA Synthesis

The repair pathways considered to this point generally work only for lesions in double-stranded DNA, the undamaged strand providing the correct genetic information to restore the damaged strand to its original state. However, in certain types of lesions, such as double-strand breaks, double-strand cross-links, or lesions in a single-stranded DNA, the complementary strand is itself damaged or is absent. **P3** Double-strand breaks and lesions in single-stranded DNA most often arise when a replication fork encounters an unrepaired DNA lesion (**Fig. 25-28**). Such lesions and DNA cross-links can also result from ionizing radiation and oxidative reactions.

At a stalled bacterial replication fork, there are two avenues for repair. In the absence of a second strand, the information required for accurate repair must come from a separate, homologous chromosome. The repair system thus involves homologous genetic recombination. This recombinational DNA repair is considered in

FIGURE 25-28 DNA damage and its effect on DNA replication. If the replication fork encounters an unrepaired lesion or strand break, the DNA polymerase sometimes disengages and re-initiates downstream. The lesion remains in an unreplicated, single-stranded gap that is left behind the replication fork (left). In other cases, a replication fork may encounter a lesion that is actively undergoing repair such that a transient break is present in one of the template strands. When the replication fork encounters it, the single-strand break becomes a double-strand break (right). In each case, the damage to one strand cannot be repaired by mechanisms described earlier in this chapter, because the complementary strand required to direct accurate repair is damaged or absent. There are at least two possible avenues for repair: recombinational DNA repair or, when lesions are unusually numerous, error-prone repair. The latter mechanism involves translesion DNA polymerases such as DNA polymerase V, encoded by the *umuC* and *umuD* genes and activated by the RecA protein that can replicate, albeit inaccurately, over many types of lesions. The repair mechanism is "error-prone" because mutations often result.

detail in Section 25.3. Under some conditions, a second repair pathway, **error-prone translesion DNA synthesis** (often abbreviated TLS), becomes available. When this pathway is active, DNA repair is significantly less accurate, and a high mutation rate can result. In bacteria, error-prone translesion DNA synthesis is part of a cellular stress response to extensive DNA damage known, appropriately enough, as the **SOS response**.

Some of the 40 or more SOS proteins, such as the UvrA and UvrB proteins involved in the error-free nucleotide-excision repair already described, are normally present in the cell but are induced to higher levels as part of the SOS response. Additional SOS proteins participate in the pathway for error-prone repair; these include the UmuC and UmuD proteins (*unmu*table; lack of the *umu* gene eliminates error-prone repair). The UmuD protein is cleaved in an SOS-regulated process to a shorter form called UmuD′, which forms a complex with UmuC and a protein called RecA (described in Section 25.3) to create a specialized DNA polymerase, DNA polymerase V (UmuD′$_2$UmuCRecA), which can replicate past many of the DNA lesions that would normally block replication. Proper base pairing is often impossible at the site of such a lesion, so this translesion replication is error-prone.

Given the emphasis on the importance of genomic integrity throughout this chapter, the existence of a system that increases the rate of mutation may seem incongruous. However, we can think of this system as a desperation strategy. The *umuC* and *umuD* genes are fully induced only late in the SOS response, and they are not activated for translesion synthesis initiated by UmuD cleavage unless the levels of DNA damage are particularly high and all replication forks are blocked. The mutations resulting from DNA polymerase V–mediated replication kill some cells and create deleterious mutations in others, but this is the biological price a species pays to overcome an otherwise insurmountable barrier to replication, as it permits at least a few mutant daughter cells to survive. P3 The resultant mutations contribute to evolution.

Yet another DNA polymerase, DNA polymerase IV, is also induced during the SOS response. Replication by DNA polymerase IV, a product of the *dinB* gene, is also highly error-prone. The bacterial DNA polymerases IV and V (Table 25-1) are part of a family of TLS polymerases found in all organisms. These enzymes lack a proofreading exonuclease and have a more open active site than other DNA polymerases, one that accommodates damaged template nucleotides. With these enzymes, the fidelity of base selection during replication may be reduced by a factor of 10^2, lowering overall replication fidelity to one error in ~1,000 nucleotides.

P4 Mammals have many low-fidelity DNA polymerases of the TLS polymerase family. However, the presence of these enzymes does not necessarily translate into an unacceptable mutational burden, because most of the enzymes also have specialized functions in DNA repair. DNA polymerase η (eta), for example, found in all eukaryotes, promotes translesion synthesis primarily across cyclobutane T–T dimers. Few mutations result, because the enzyme preferentially inserts two A residues across from the linked T residues. Several other low-fidelity polymerases, including DNA polymerases β, ι (iota), and λ, have specialized roles in eukaryotic base-excision repair. Each of these enzymes has a 5′-deoxyribose phosphate lyase activity in addition to its polymerase activity. After base removal by a glycosylase and backbone cleavage by an AP endonuclease, these polymerases remove the abasic site (a 5′-deoxyribose phosphate) and fill in the very short gap. The frequency of mutation due to DNA polymerase η activity is minimized by the short lengths (often one nucleotide) of DNA synthesized.

What emerges from research into cellular DNA repair systems is a picture of a DNA metabolism that maintains genomic integrity with multiple and often redundant systems. Most of the major DNA repair systems occur in all organisms. P4 These repair systems are often integrated with the DNA replication systems and are complemented by recombination systems, which we turn to next.

SUMMARY 25.2 ***DNA Repair***

- Mutations are genomic changes that alter the information in DNA. When mutations occur in genes encoding enzymes involved in DNA repair, the loss of function can lead to cancer.
- Cells have many systems for DNA repair. Major repair systems present in all organisms include mismatch repair, base excision repair, nucleotide-excision repair, and direct repair.
- In bacteria, TLS DNA polymerases respond to very heavy DNA damage with error-prone translesion DNA synthesis. In eukaryotes, similar polymerases have specialized roles in DNA repair that minimize the introduction of mutations.

25.3 DNA Recombination

The rearrangement of genetic information within and among DNA molecules encompasses a variety of processes, collectively placed under the heading of genetic recombination. The practical applications of DNA rearrangements in altering the genomes of increasing numbers of organisms are now being explored (Chapter 9).

Barbara McClintock, 1902–1992

[AP Photo.]

Genetic recombination events fall into at least three general classes. **Homologous genetic recombination** (also called general recombination) involves genetic exchanges between any two DNA molecules (or segments of the same molecule) that share an extended region of nearly identical sequence. The actual sequence of bases is irrelevant, as long as it is similar in the two DNAs. In **site-specific recombination**, the exchanges occur only at a *particular* DNA sequence. **DNA transposition** is distinct from both other classes in that it usually involves a short segment of DNA with the remarkable capacity to move from one location in a chromosome to another. These "jumping genes" were first observed in maize in the 1940s by Barbara McClintock. There are also unusual genetic rearrangements for which no mechanism or purpose has yet been proposed. Here we focus on the three general classes.

Homologous genetic recombination is largely a pathway to repair double-strand breaks in DNA. An alternative process for double-strand break repair that does not entail recombination, called **nonhomologous end joining (NHEJ)**, is also described here. Genetic recombination systems have functions as varied as their mechanisms. They include roles in specialized DNA repair systems, specialized activities in DNA replication, regulation of expression of certain genes, facilitation of proper chromosome segregation during eukaryotic cell division, maintenance of genetic diversity, and implementation of programmed genetic rearrangements during embryonic development. In most cases, genetic recombination is closely integrated with other processes in DNA metabolism, and this becomes a theme of our discussion.

Bacterial Homologous Recombination Is a DNA Repair Function

P4 In bacteria, homologous genetic recombination is primarily a DNA repair process, and in this context (as noted in Section 25.2) it is referred to as **recombinational DNA repair**. It is usually directed at the reconstruction of replication forks that have stalled or collapsed at the site of DNA damage. Homologous genetic recombination can also occur during conjugation (mating), when chromosomal DNA is transferred from one bacterial cell (donor) to another (recipient). Recombination during conjugation, although rare in wild bacterial populations, contributes to genetic diversity.

P4 When a replication fork encounters DNA damage, many pathways may resolve the conflict. A common feature of the DNA repair pathways illustrated in Figures 25-21 to 25-24 is that they introduce a transient break into one of the DNA strands. If a replication fork encounters a damaged site under repair near a break in one of the template strands, one arm of the replication fork becomes disconnected by a double-strand break and the fork collapses (**Fig. 25-29**). The end of that break is processed by degrading the 5′-ending strand. The resulting 3′ single-stranded extension is bound by a recombinase

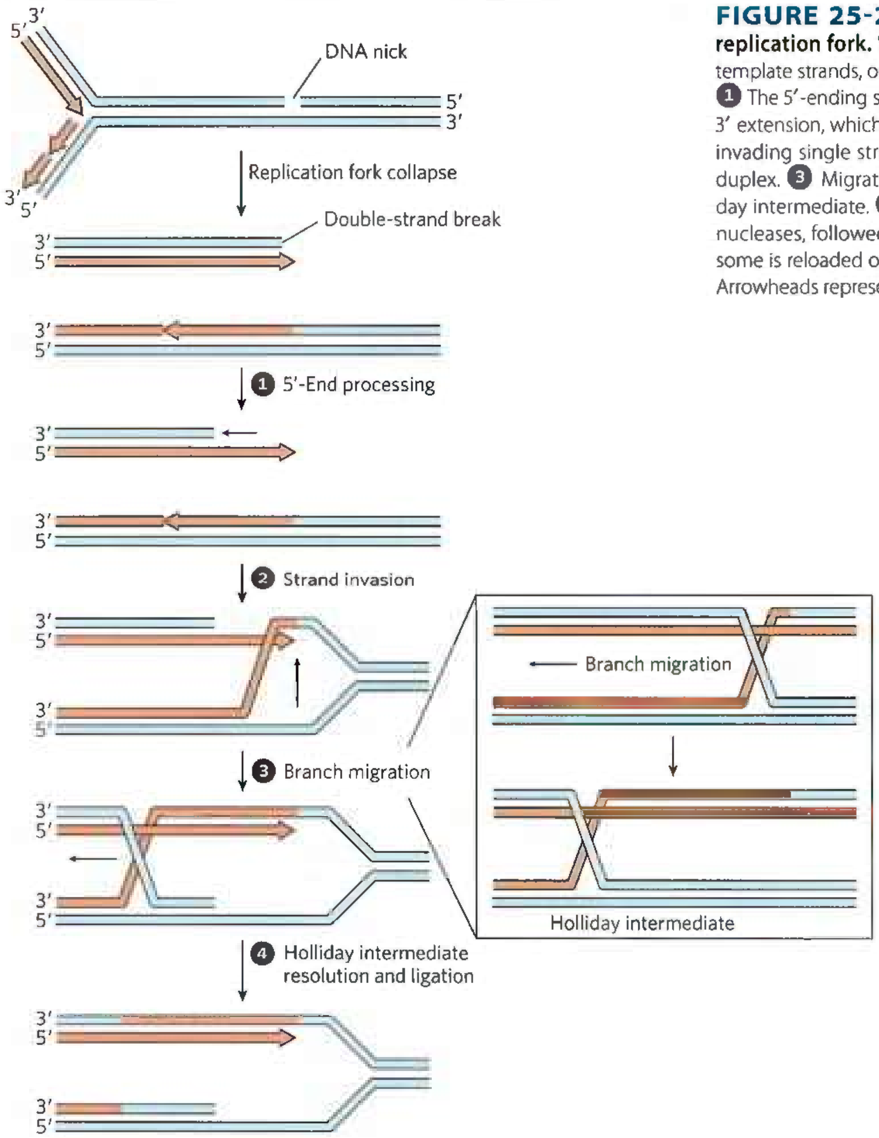

FIGURE 25-29 Recombinational DNA repair at a collapsed replication fork. When a replication fork encounters a break in one of the template strands, one arm of the fork is lost and the replication fork collapses. ① The 5′-ending strand at the break is degraded to create a single-stranded 3′ extension, which is then used in ② a strand invasion process, pairing the invading single strand with its complementary strand within the adjacent duplex. ③ Migration of the branch (shown in the box) can create a Holliday intermediate. ④ Cleavage of the Holliday intermediate by specialized nucleases, followed by ligation, restores a viable replication fork. The replisome is reloaded onto this structure (not shown), and replication continues. Arrowheads represent 3′ ends.

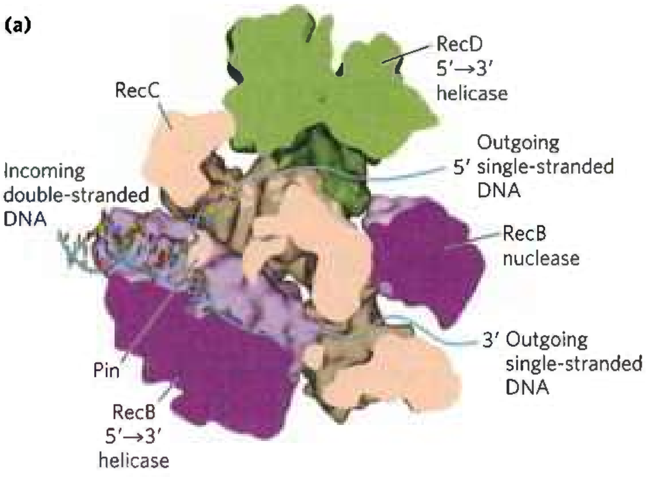
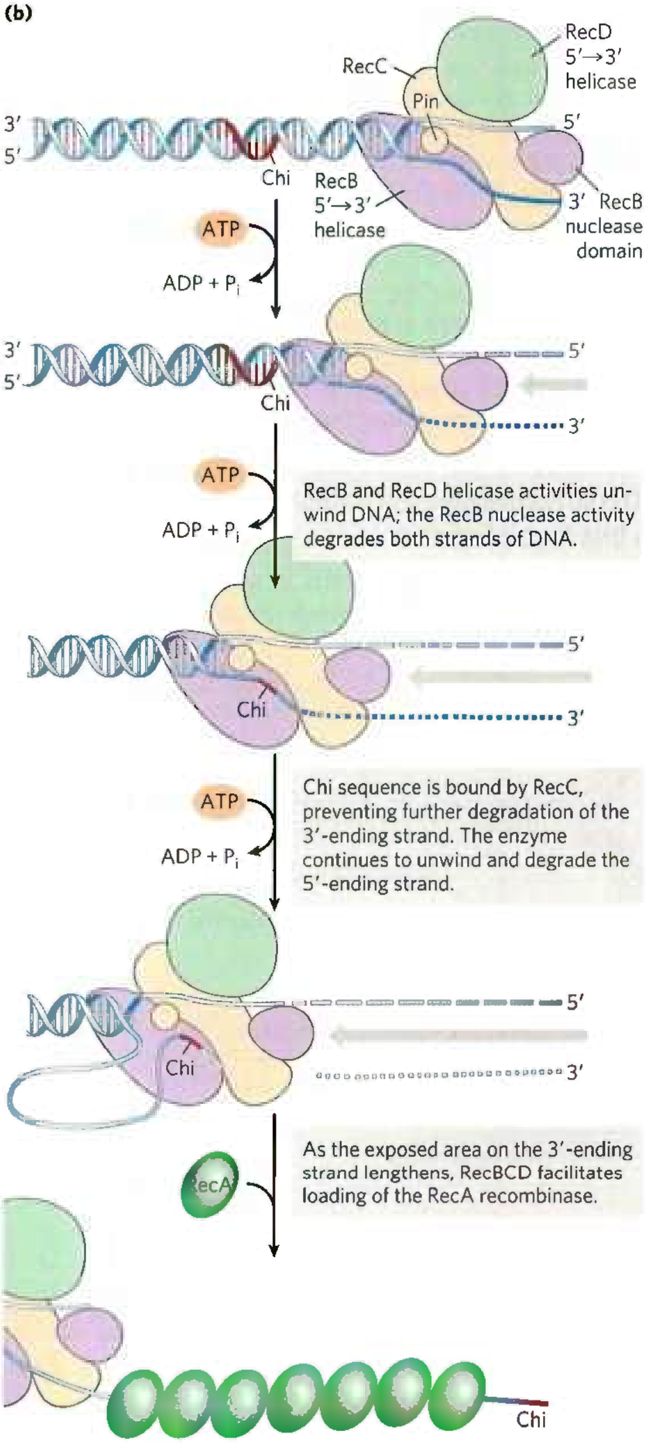
(a)



(b)



RecB and RecD helicase activities unwind DNA; the RecB nuclease activity degrades both strands of DNA.

Chi sequence is bound by RecC, preventing further degradation of the 3′-ending strand. The enzyme continues to unwind and degrade the 5′-ending strand.

As the exposed area on the 3′-ending strand lengthens, RecBCD facilitates loading of the RecA recombinase.

FIGURE 25-30 The RecBCD helicase/nuclease. (a) A cutaway view of the RecBCD enzyme structure as it is bound to DNA. The subunits are shown in different colors; the DNA is entering from the left, and the unwound DNA strands (not part of the solved structure) are shown exiting to the right. A bulbous protein structure called a pin, part of the RecC subunit, facilitates the separation of strands. (b) Activities of the RecBCD enzyme at a DNA end. [(a) Data from PDB ID 1W36, M. R. Singleton et al., *Nature* 432:187, 2004.]

that uses it to promote strand invasion: the 3′ end invades the intact duplex DNA connected to the other arm of the fork and pairs with its complementary sequence. This creates a branched DNA structure (a point where three DNA segments come together). The DNA branch can be moved in a process called **branch migration** to create an X-like crossover structure known as a **Holliday intermediate**, named after researcher Robin Holliday, who first postulated its existence. The Holliday intermediate is cleaved, or "resolved," by a special class of nucleases. The overall process reconstructs the replication fork.

In *E. coli*, the DNA end-processing is promoted by the RecBCD nuclease/helicase. The RecBCD enzyme binds to linear DNA at a free (broken) end and moves inward along the double helix, unwinding and degrading the DNA in a reaction coupled to ATP hydrolysis (**Fig. 25-30**). The RecB and RecD subunits are helicase motors, with RecB moving 3′→5′ along one strand, and RecD moving 5′→3′ along the other strand. The activity of the enzyme is altered when it interacts with a sequence referred to as **chi**, (5′)GCTGGTGG, which binds tightly to a site on the RecC subunit. From that point, degradation of the strand with a 3′ terminus is greatly reduced, but degradation of the 5′-terminal strand is increased. This process creates a single-stranded DNA with a 3′ end, which is used during subsequent steps in recombination. The 1,009 chi sequences scattered throughout the *E. coli* genome enhance the frequency of recombination about 5- to 10-fold within 1,000 bp of each chi site. The enhancement declines as the distance from chi increases. Sequences that enhance recombination frequency have also been identified in several other organisms.

The bacterial recombinase is the RecA protein. RecA is unusual among the proteins of DNA metabolism in that its active form is an ordered, helical filament of up to several thousand subunits that assemble cooperatively on DNA (**Fig. 25-31**). This filament usually forms on single-stranded DNA, such as that produced by the RecBCD enzyme. Its formation is not as straightforward as shown in Figure 25-31, because the single-stranded DNA–binding protein (SSB) is normally present and

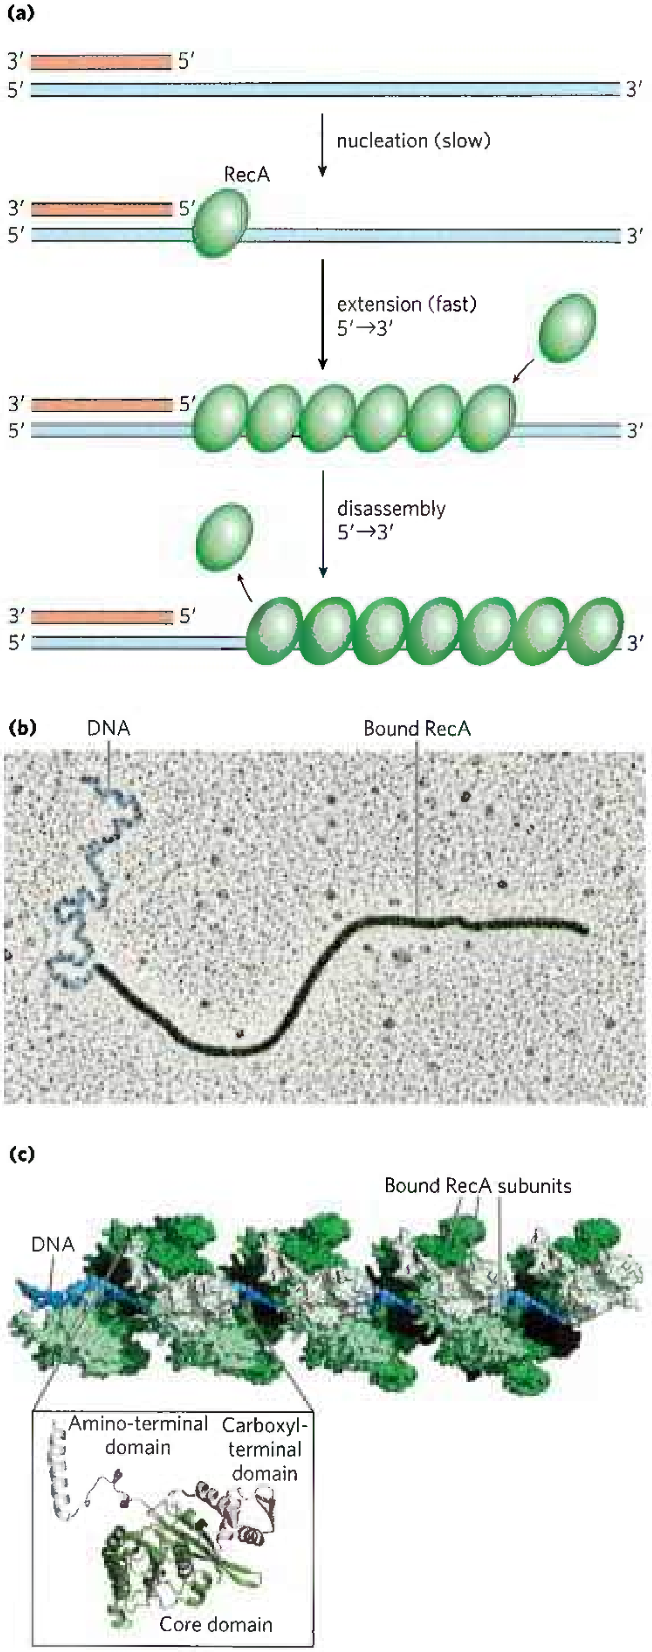


FIGURE 25-31 RecA protein filaments. RecA and other recombinases in this class function as filaments of nucleoprotein. (a) Filament formation proceeds in discrete nucleation and extension steps. Nucleation is the addition of the first few RecA subunits. Extension occurs by adding RecA subunits so that the filament grows in the 5′→3′ direction. When disassembly occurs, subunits are subtracted from the trailing end. (b) Colorized electron micrograph of a RecA filament bound to DNA. (c) Segment of a RecA filament with four helical turns (24 RecA subunits). Notice the bound double-stranded DNA in the center. The core domain of RecA is structurally related to the motor domains of helicases. [(b) By permission of the Estate of Ross Inman. Special thanks to Kim Voss. (c) Data from PDB ID 3CMX, Z. Chen et al., *Nature* 453:489, 2008.]

specifically impedes the binding of the first few subunits to DNA (filament nucleation). The RecBCD enzyme acts directly as a RecA loader, facilitating the nucleation of a RecA filament on single-stranded DNA that is coated with SSB. The filaments assemble and disassemble predominantly in a 5′→3′ direction. Many other bacterial proteins regulate the formation and disassembly of RecA filaments, including an alternative set of RecA loading proteins called RecF, RecO, and RecR. RecA protein promotes the central steps of homologous recombination, including the DNA strand invasion step of Figure 25-29, as well as other strand exchange reactions occurring in vitro. Once a Holliday intermediate has been created via branch migration, it can be cleaved by specialized nucleases such as the bacterial RuvC protein (**Fig. 25-32**), and nicks are sealed by DNA ligase. A viable replication fork structure is thus reconstructed, as outlined in Figure 25-29.

After the recombination steps are completed, the replication fork reassembles in a process called **origin-independent restart of replication**. Different combinations of four proteins (PriA, PriB, PriC, and DnaT) act with DnaC in several pathways to load DnaB helicase onto the reconstructed replication fork. The DnaG primase then synthesizes an RNA primer, and DNA polymerase III reassembles on DnaB to restart DNA synthesis. Complexes that include some combination of the PriA, PriB, PriC, and DnaT, along with DnaB, DnaC, and DnaG proteins, are called **replication restart primosomes**. In this way, the process of recombination is tightly intertwined with replication. One process of DNA metabolism supports the other.

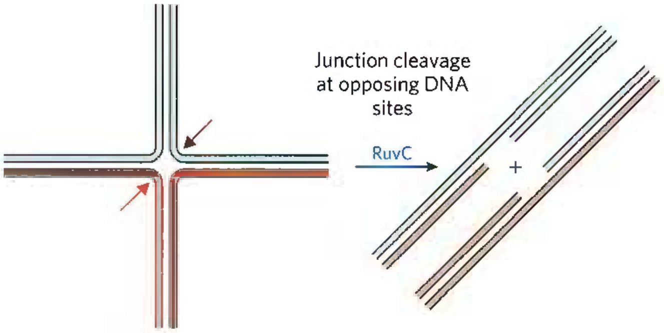

FIGURE 25-32 Resolution of a Holliday intermediate by the RuvC protein. RuvC is a specialized nuclease that binds to the RuvAB complex and cleaves the Holliday intermediate on opposing sides of the crossover junction (red arrows), so that two contiguous DNA arms remain in each product.

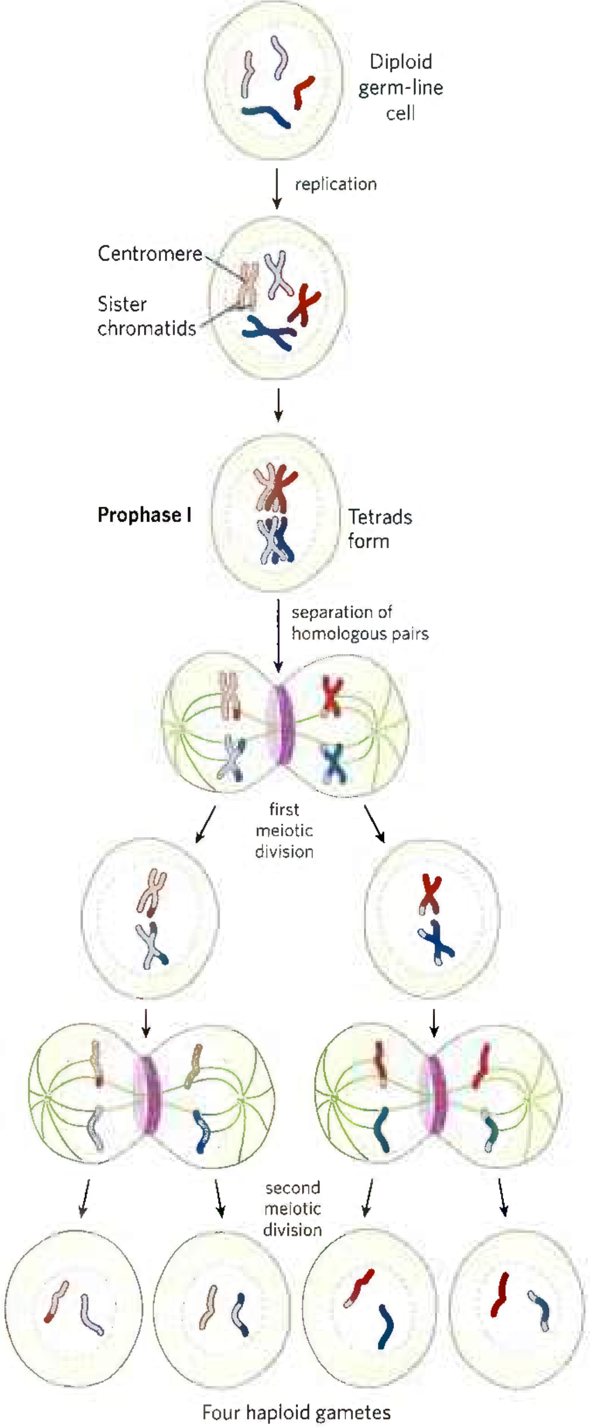
Eukaryotic Homologous Recombination Is Required for Proper Chromosome Segregation during Meiosis

In eukaryotes, homologous genetic recombination has roles in replication and cell division, including the repair of stalled replication forks. Recombination occurs with the highest frequency during **meiosis**, the process by which diploid germ-line cells with two sets of chromosomes divide to produce haploid gametes (sperm cells or ova) in animals (haploid spores in plants) — each gamete having only one member of each chromosome pair (**Fig. 25-33**).

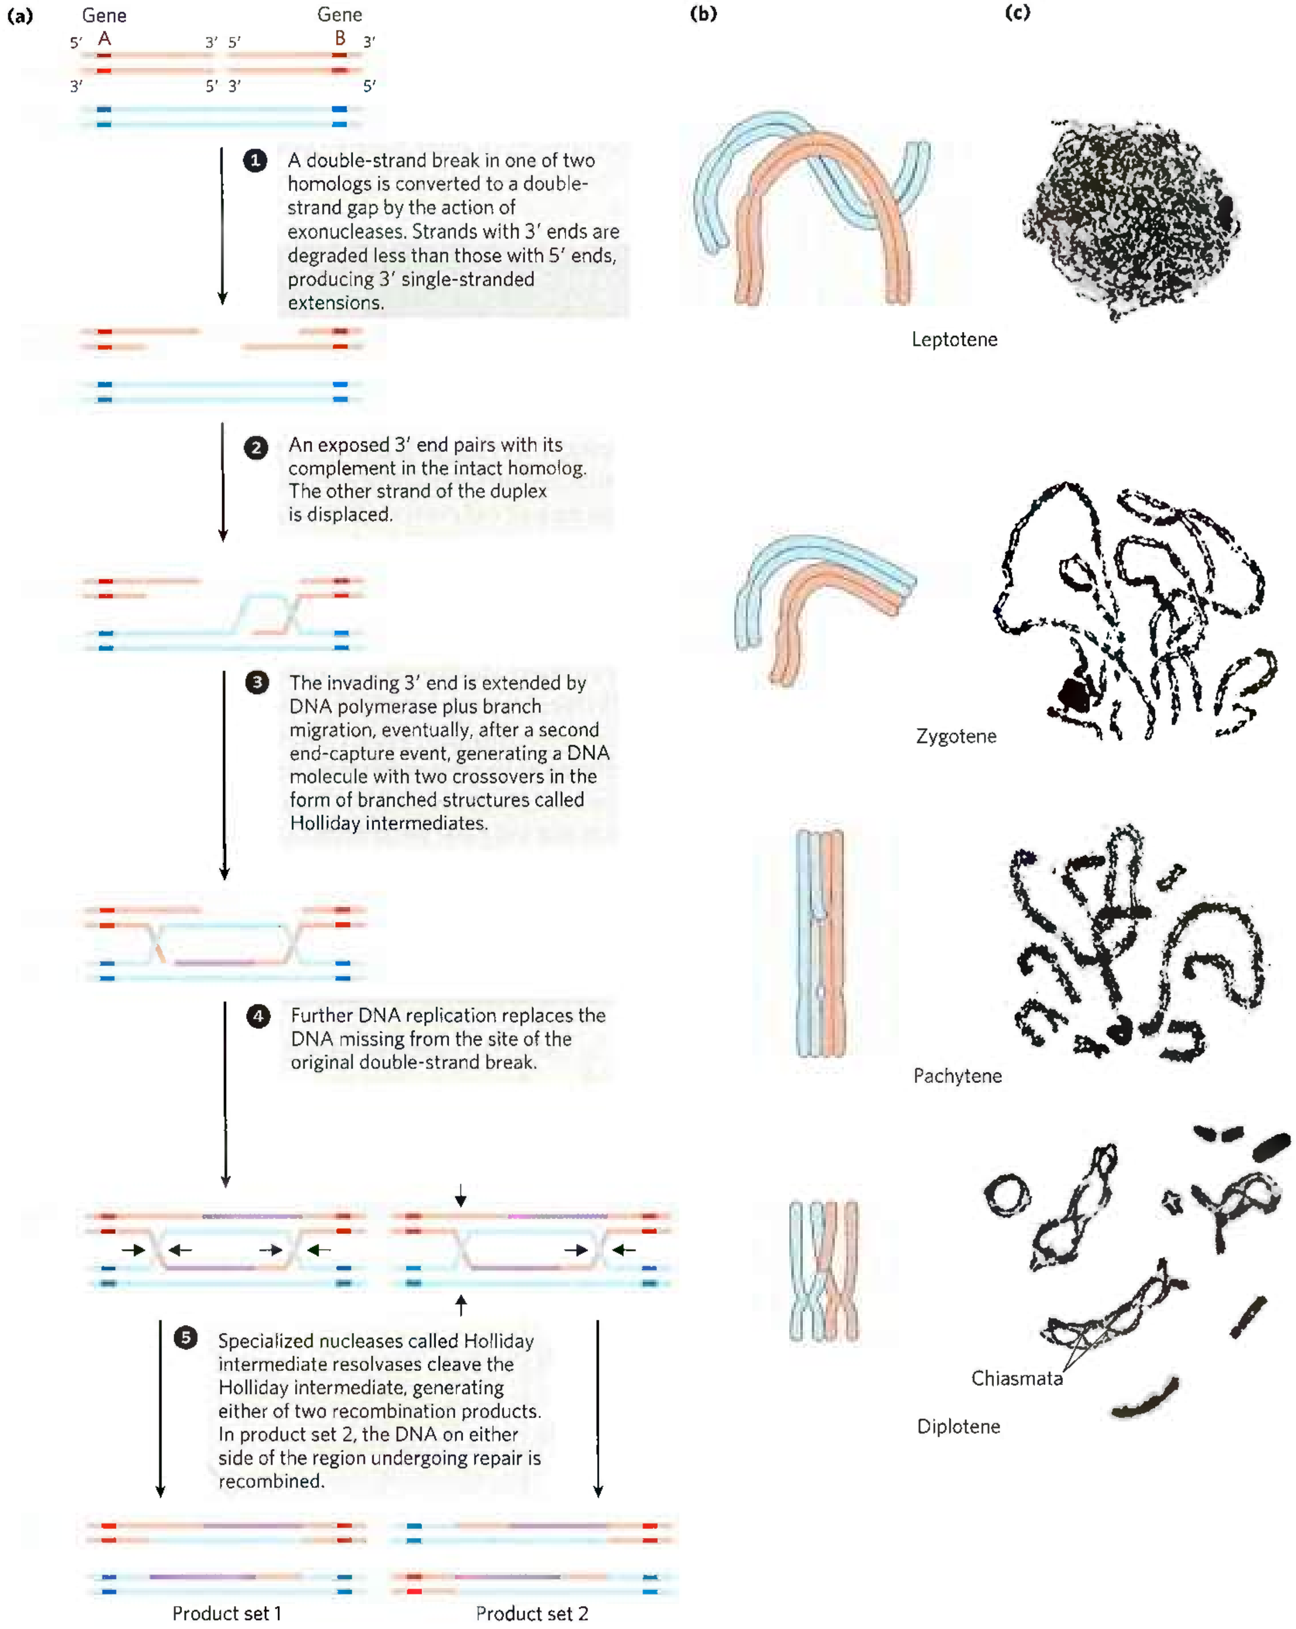


Meiosis begins with replication of the DNA in the germ-line cell so that each DNA molecule is present in four copies. Each set of four homologous chromosomes (tetrad) exists as two pairs of sister chromatids, and the sister chromatids remain associated at their centromeres. The cell then goes through two rounds of cell division without an intervening round of DNA replication. In the first cell division, the two pairs of sister chromatids are segregated into daughter cells. In the second cell division, the two chromosomes in each sister chromatid pair are segregated into new daughter cells. In each division, the chromosomes to be segregated are drawn into the daughter cells by spindle fibers attached to opposite poles of the dividing cell. The two successive divisions reduce the DNA content to the haploid level in each gamete.

Proper chromosome segregation into daughter cells requires that physical links exist between the homologous chromosomes to be segregated. As the spindle fibers attach to the centromeres of chromosomes and start to pull, the links between homologous chromosomes create tension. This tension, sensed by cellular mechanisms not yet understood, signals that this pair of chromosomes or sister chromatids is properly aligned for segregation. Once the tension is sensed, the links are gradually dissolved and segregation proceeds. If improper spindle fiber attachment occurs (e.g., if the centromeres of a chromosome pair are attached to the same cellular pole), a cellular kinase senses the lack of tension and activates a system that removes the spindle attachments, allowing the cell to try again.

During the second meiotic division, the centromeric attachments between sister chromatids, augmented by cohesins deposited during replication (see Fig. 24-33), provide the physical links that are needed to guide segregation. However, during the first meiotic cell division, the two pairs of sister chromatids to be segregated are not related by a recent replication event and are not linked by cohesins or any other physical association. Instead, the homologous pairs of sister chromatids are aligned and new links are created by recombination, a process involving the breakage and rejoining of DNA (**Fig. 25-34**).

FIGURE 25-33 Meiosis in animal germ-line cells. The chromosomes of a hypothetical diploid germ-line cell (four chromosomes; two homologous pairs) replicate and are held together at their centromeres. Each replicated double-stranded DNA molecule is called a chromatid (sister chromatid). In prophase I, just before the first meiotic division, the two homologous sets of chromatids align to form tetrads, held together by covalent links at homologous junctions (chiasmata). Crossovers occur within the chiasmata (see Fig. 25-34). These transient associations between homologs ensure that the two tethered chromosomes segregate properly in the next step, when attached spindle fibers pull them toward opposite poles of the dividing cell in the first meiotic division. The products of this division are two daughter cells, each with two pairs of different sister chromatids. The pairs now line up across the equator of the cell in preparation for separation of the chromatids (now called chromosomes). The second meiotic division produces four haploid daughter cells that can serve as gametes. Each has two chromosomes, half the number of the diploid germ-line cell. The chromosomes have re-sorted and recombined.



❶ A double-strand break in one of two homologs is converted to a double-strand gap by the action of exonucleases. Strands with 3′ ends are degraded less than those with 5′ ends, producing 3′ single-stranded extensions.

❷ An exposed 3′ end pairs with its complement in the intact homolog. The other strand of the duplex is displaced.

❸ The invading 3′ end is extended by DNA polymerase plus branch migration, eventually, after a second end-capture event, generating a DNA molecule with two crossovers in the form of branched structures called Holliday intermediates.

❹ Further DNA replication replaces the DNA missing from the site of the original double-strand break.

❺ Specialized nucleases called Holliday intermediate resolvases cleave the Holliday intermediate, generating either of two recombination products. In product set 2, the DNA on either side of the region undergoing repair is recombined.

FIGURE 25-34 Recombination during prophase I in meiosis. (a) A model of double-strand break repair for homologous genetic recombination. The two homologous chromosomes (one shown in red, the other blue) involved in this recombination event have identical or very nearly identical sequences. Each of the two genes shown has different alleles on the two chromosomes. The steps are described in the text. (b) Crossing over occurs during prophase of meiosis I. The several stages of prophase I are aligned with the recombination processes shown in (a). Double-strand breaks are introduced and processed in the leptotene stage. The strand invasion and completion of crossover occur later. As homologous sequences in the two pairs of sister chromatids are aligned in the zygotene stage, synaptonemal complexes form and strand invasion occurs. The homologous chromosomes are tightly aligned by the pachytene stage. (c) Homologous chromosomes of a grasshopper, viewed at successive stages of meiotic prophase I. The chiasmata become visible in the diplotene stage. [(c) B. John, *Meiosis*, Figs 2.1a, 2.2a, 2.2b, 2.3a, Cambridge University Press, 1990. Reprinted with the permission of Cambridge University Press.]

This exchange, also referred to as crossing over, can be observed with the light microscope. Crossing over links the two pairs of sister chromatids together at points called chiasmata (singular, chiasma). Also during crossing over, genetic material is exchanged between the pairs of sister chromatids. These exchanges increase genetic diversity in the resulting gametes. The importance of meiotic recombination to proper chromosome segregation is well illustrated by the physiological and societal consequences of their failure (**Box 25-2**).

BOX 25-2 **MEDICINE**

Why Proper Segregation of Chromosomes Matters

When chromosomal alignment and recombination are not correct and complete in meiosis I, segregation of chromosomes can go awry. One result may be aneuploidy, a condition in which a cell has the wrong number of chromosomes. The haploid products of meiosis (gametes or spores) may have no copies or two copies of a chromosome. When a gamete having two copies of a chromosome joins with a gamete having one copy of a chromosome during fertilization, cells in the resulting embryo have three copies of that chromosome (they are trisomic).

In *S. cerevisiae*, aneuploidy resulting from errors in meiosis occurs at a rate of about 1 in 10,000 meiotic events. In fruit flies, the rate is about 1 in a few thousand. Rates of aneuploidy in mammals are considerably higher. In mice, the rate is 1 in 100, and it is even higher in other mammals. The rate of aneuploidy in fertilized human eggs has been estimated as 10% to 30%; this is almost certainly an underestimate. Most of these aneuploid cells are monosomies (they have a single copy of a chromosome) or trisomies. Most trisomies are lethal, and many result in miscarriage long before the pregnancy is detected. Almost all monosomies are fatal in the early stages of fetal development. Aneuploidy is the leading cause of pregnancy loss. The few trisomic fetuses that survive to birth generally have three copies of chromosome 13, 18, or 21 (trisomy 21 is Down syndrome). Abnormal complements of the sex chromosomes are also found in the human population. The societal consequences of aneuploidy in humans are considerable. Aneuploidy is the leading genetic cause of developmental and mental disabilities. At the heart of these high rates is a feature of meiosis in female mammals that has special significance for the human species.

In a human male, germ-line cells begin to undergo meiosis at puberty, and each meiotic event requires a relatively short time. In contrast, meiosis in the germ-line cells of human females is a highly protracted process. The production of an egg begins before a female is born, with the onset of meiosis in the fetus, at 12 to 13 weeks of gestation. Meiosis is initiated in all the developing fetal germ-line cells over a period of a few weeks. The cells proceed through much of meiosis I. Chromosomes line up and generate crossovers, continuing just beyond the pachytene stage (see Fig. 25-34)—and then the process stops. The chromosomes enter an arrested phase called the dictyate stage, with the crossovers in place, a kind of suspended animation where they remain as the female matures—so, typically remaining in this stage for anywhere from about 13 to 50 years. At sexual maturity, individual germ-line cells continue through the two meiotic cell divisions to produce egg cells.

Between the onset of the dictyate stage and the final completion of meiosis, something may happen that disrupts or damages the crossovers linking homologous chromosomes in the germ-line cells. As a woman ages, the rate of trisomy in the egg cells she produces increases, dramatically so as she approaches menopause (Fig. 1). There are many hypotheses on why this occurs, and several different factors may play a role. However, most of the hypotheses are centered on recombination crossovers in meiosis I and their stability over the protracted dictyate stage.

It is not yet clear what medical steps could be taken to reduce the incidence of aneuploidy in women of child-bearing age. What is revealed is the inherent importance of recombination and generation of crossovers in human meiosis.

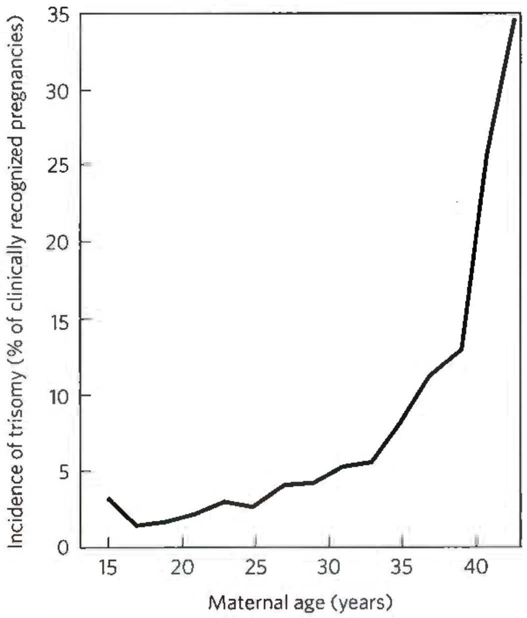


FIGURE 1 The increasing incidence of human trisomy with increasing age of the mother. [Data from T. Hassold and P. Hunt, *Nat. Rev. Genet.* 2:280, 2001, Fig. 6.]

A likely pathway for homologous recombination during meiosis is outlined in Figure 25-34a. The model has four key features. First, homologous chromosomes align. Second, a double-strand break is created in a DNA molecule, and the exposed ends are processed by an exonuclease, leaving a single-stranded extension with a free 3′-hydroxyl group at the broken end (step ①). Third, the exposed 3′ ends invade the intact duplex DNA of the homolog, and this is followed by branch migration and/or replication to create a pair of Holliday intermediates (steps ② to ④). Fourth, cleavage of the two crossovers creates either of two pairs of complete recombinant products (step ⑤). Notice the similarity of these steps to the bacterial recombinational repair processes outlined in Figure 25-29. The DNA strand invasion in eukaryotes is catalyzed by RecA-like recombinases called Rad51 and Dmc1. Loading of Rad51 onto DNA is promoted by Rad51 loading protein BRCA2 (analogous to the bacterial RecF, RecO, and RecR proteins).

In this **double-strand break repair model** for recombination, the 3′ ends are used to initiate the genetic exchange. Once paired with the complementary strand on the intact homolog, a region of hybrid DNA is created that contains complementary strands from two different parent DNAs (the product of step ② in Fig. 25-34a). Each of the 3′ ends can then act as a primer for DNA replication. Meiotic homologous recombination can vary in many details from one species to another, but most of the steps outlined above are generally present in some form. There are two ways to resolve the Holliday intermediate with a RuvC-like nuclease so that the two products carry genes in the same linear order as in the substrates—the original, unrecombined chromosomes (step ⑤). If cleaved one way, the DNA flanking the region containing the hybrid DNA is not recombined; if cleaved the other way, the flanking DNA is recombined. Both outcomes are observed in vivo.

The homologous recombination illustrated in Figure 25-34 is an elaborate process that is essential to accurate chromosome segregation. Its molecular consequences for the generation of genetic diversity are subtle. To understand how this process contributes to diversity, we should keep in mind that the two homologous chromosomes that undergo recombination are not necessarily *identical*. The linear array of genes may be the same, but the base sequences in some of the genes may differ slightly (in different alleles). In a human, for example, one chromosome may contain the allele for hemoglobin A (normal hemoglobin) while the other contains the allele for hemoglobin S (the sickle cell mutation). The difference may consist of no more than one base pair among millions.

Crossing over is not an entirely random process, and "hot spots" have been identified on many eukaryotic chromosomes. However, the assumption that crossing over can occur with equal probability at almost any point along the length of two homologous chromosomes remains a reasonable approximation in many cases, and it is this assumption that permits the mapping of genes on a particular chromosome. The frequency of homologous recombination in any region separating two points on a chromosome is roughly proportional to the distance between the points, and this allows determination of the relative positions of different genes and the distances between those genes. The independent assortment of unlinked genes on different chromosomes (**Fig. 25-35**)

FIGURE 25-35 The contribution of independent assortment to genetic diversity. In this example, the two chromosomes have already been replicated to create two pairs of sister chromatids. Blue and red distinguish the sister chromatids of each pair. One gene on each chromosome is highlighted, with different alleles (*A* or *a*, *B* or *b*) in the homologs. Independent assortment can lead to gametes with any combination of the alleles present on the two different chromosomes. Crossing over (not shown here; see Fig. 25-34) would also contribute to genetic diversity in a typical meiotic sequence.

makes another major contribution to the genetic diversity of gametes. These genetic realities guide many of the modern applications of genomics, such as defining haplotypes (see Fig. 9-26) or searching for disease genes in the human genome (see Fig. 9-30).

As in bacteria, this recombination process is used to repair double-strand breaks that arise anywhere in the genome. In eukaryotes, these systems operate in the context of chromatin, rendering additional complexities to their regulation and damage detection mechanisms (**Box 25-3**). **P3** Homologous recombination thus serves at least three identifiable functions in eukaryotes: (1) it contributes to the repair of several types of DNA damage; (2) it provides, in eukaryotic cells, a transient physical link between chromatids that promotes the orderly segregation of chromosomes at the first meiotic cell division; and (3) it enhances genetic diversity in a population.

Some Double-Strand Breaks Are Repaired by Nonhomologous End Joining

Double-strand breaks sometimes occur when recombinational DNA repair is not feasible, such as during phases of the cell cycle when no replication is occurring and no sister chromatids are present. At these times, another path is needed to avoid the cell death that would result from a broken chromosome. That alternative is provided by **nonhomologous end joining (NHEJ)**. The broken chromosome ends are simply processed and ligated back together.

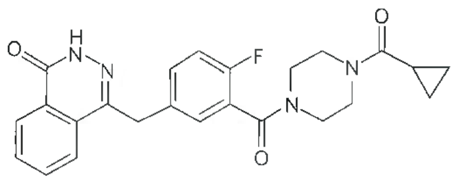
Nonhomologous end joining is an important pathway for double-strand break repair in all eukaryotes and has also been detected in some bacteria. The importance of NHEJ increases with genomic complexity, and the process accounts for most double-strand break

BOX 25-3 MEDICINE

How a DNA Strand Break Gets Attention

Each human chromosome contains many millions of DNA base pairs, all bound up in an elaborate chromatin structure (Chapter 24). If a strand break occurs somewhere in the DNA, how do the many proteins needed for its repair actually find it? The answer lies, at least in part, in a protein called poly-ADP ribose polymerase 1, or PARP1. PARP1 is a first responder, scanning the DNA for DNA damage and in particular for single-strand breaks. When it finds such sites, it binds and synthesizes an elaborate branched poly-ADP ribose polymer from an NAD precursor (Fig. 1). The polymers are attached to the PARP1 enzyme and also linked to some nearby proteins through Glu, Asp, or Lys residues. The resulting structure is a kind of signal, marking the chromosomal location of damage. A large number of DNA repair proteins bind to and are thus recruited to the poly-ADP ribose polymers, effecting DNA repair. If PARP1 activity is absent, repair is compromised and the number of single-strand breaks in all chromosomes increases. When the chromosome is replicated, the single-strand breaks become double-strand breaks (see Fig. 25-29).

As we saw in Box 25-1, many malignant tumors have a defect in a DNA repair pathway. For example, breast or ovarian cancer is often associated with defects in double-strand break repair (e.g., in the genes encoding BRCA1 or BRCA2 or other proteins in the pathway). In these cells, the further loss of PARP1 activity is especially toxic, as single-strand breaks build up and chromosomes become broken during replication. This has led to the development of PARP1 inhibitors as a treatment for tumors in which double-strand break repair is defective. The first such pharmaceutical agent, olaparib, was approved for use in the United States in 2014. Many more PARP1 inhibitors have since been approved or are undergoing clinical trials. The effects have often been dramatic. For women with breast or ovarian tumors displaying deficiencies in BRCA1 or BRCA2 that have responded to more traditional therapies, subsequent maintenance treatment with PARP1 inhibitors has led to a fourfold increase in progression-free survival. PARP1 inhibitors are also showing promise for use with other breast and ovarian tumors, as well as other types of tumors, most of which have DNA repair deficiencies of some kind. As research continues, the use of PARP inhibitors is becoming an important part of the standard of care for a growing list of cancers.



Olaparib

repair outside meiosis in mammals. In yeast, most double-strand breaks are repaired by recombination, and only a few by NHEJ. NHEJ is a mutagenic process, and a smaller genome, such as that of yeast, has relatively little tolerance for the loss of information. The small genomic alterations may be tolerable in mammalian somatic cells, because they are balanced by the undamaged information on the homolog in each diploid cell, and in these non-germ-line cells the mutations are not inherited. In vertebrates, a loss of the genes encoding NHEJ function can produce a predisposition to cancer.

Unlike homologous recombinational repair, NHEJ does not conserve the original DNA sequence. The pathway in eukaryotes is illustrated in **Figure 25-36**. The reaction is initiated at the broken ends of a double-strand break by the binding of a heterodimer consisting of the proteins Ku70 and Ku80 ("KU" being the initials of the individual with scleroderma whose serum autoantibodies were used to identify this protein complex; the numbers refer to the approximate molecular weights of the subunits). The Ku proteins are conserved in almost all eukaryotes and act as a kind of molecular scaffold to assemble the other protein components. Ku70-Ku80 interacts with another protein complex containing a protein kinase called DNA-PKcs and a nuclease known as Artemis. Once the complex is assembled, the two broken DNA ends are synapsed (held together). DNA-PKcs autophosphorylates in several locations and also phosphorylates Artemis. Artemis, when phosphorylated, acquires an endonuclease function that can remove 5′ or 3′ single-stranded extensions or hairpins that might be present at the ends. The DNA ends are then separated with the aid of a helicase, and strands from the two different ends are annealed at locations

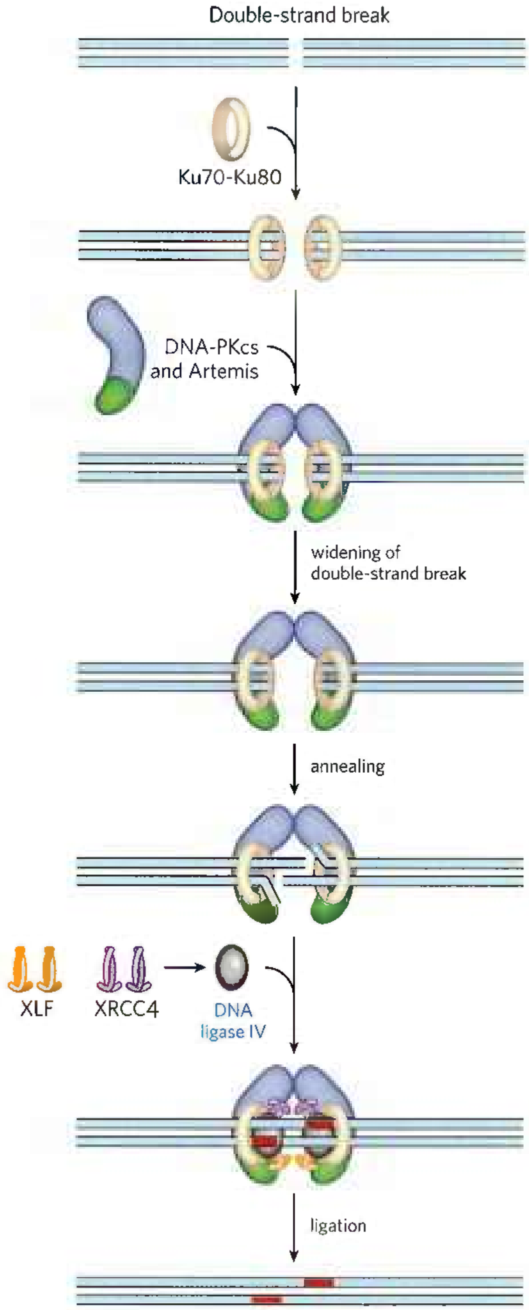

FIGURE 25-36 Nonhomologous end joining. The Ku70-Ku80 complex is the first to bind the DNA ends, followed by a complex including DNA-PKcs and the nuclease Artemis. These proteins then recruit a complex consisting of XRCC4, XLF, and DNA ligase IV. Either of two DNA polymerases, Pol μ or Pol λ (not shown), subsequently extends the annealed DNA strands, as needed, before ligation. [Information from J. M. Sekiguchi and D. O. Ferguson, *Cell* 124:260, 2006, Fig. 1.]

where short regions of complementarity are encountered. Artemis cleaves any unpaired DNA segments that are created. Small DNA gaps are filled by a DNA polymerase, Pol μ or Pol λ. Finally, the nicks are sealed by a protein complex consisting of XRCC4 (*x-r*ay *c*ross *c*omplementation group), XLF (*X*RCC4-*l*ike *f*actor), and DNA ligase IV.

DNA ends are not joined randomly by NHEJ. Instead, when a double-strand break occurs, the ends are generally constrained by the structure of chromatin and thus remain close together. Very rare events linking end sequences that are normally far apart in the chromosome, or are on different chromosomes, may be responsible for occasional dramatic and usually deleterious genomic rearrangements.

Site-Specific Recombination Results in Precise DNA Rearrangements

Homologous genetic recombination can involve any two homologous sequences. The second general type of recombination, site-specific recombination, is a very different type of process: recombination is limited to specific sequences. Recombination reactions of this type occur in virtually every cell, filling specialized roles that vary greatly from one species to another. Examples include regulation of the expression of certain genes and promotion of programmed DNA rearrangements in embryonic development or in the replication cycles of some viral and plasmid DNAs. Each site-specific recombination system consists of an enzyme called a recombinase and a short (20 to 200 bp), unique DNA sequence where the recombinase acts (the recombination site). One or more auxiliary proteins may regulate the timing or outcome of the reaction.

There are two general classes of site-specific recombination systems, which rely on either Tyr or Ser residues in the active site. In vitro studies of many site-specific recombination systems in the tyrosine class have elucidated some general principles, including the fundamental reaction pathway (**Fig. 25-37a**). Several of these enzymes have been crystallized, revealing structural details of the reaction. A separate recombinase recognizes and binds to each of two recombination sites on two different DNA molecules or within the same DNA. One DNA strand in each site is cleaved at a specific point within the site, and the recombinase becomes covalently linked to the DNA at the cleavage site through a phosphotyrosine bond (step ❶). The transient protein-DNA linkage preserves the phosphodiester bond that is lost in cleaving the DNA, so high-energy cofactors such as ATP are unnecessary in subsequent steps. The cleaved DNA strands are rejoined to new partners to form a Holliday intermediate, with new phosphodiester bonds created at the expense of the protein-DNA linkage (step ❷). An isomerization then occurs (step ❸), and the process is repeated at a second point within each of the two recombination sites (steps ❹ and ❺). In systems that employ an active-site Ser residue, both strands of each recombination site are cut concurrently and rejoined to new partners without the Holliday intermediate. In both types of systems, the exchange is always reciprocal and precise, regenerating the recombination sites when the reaction is complete. We can view a recombinase as a site-specific endonuclease and ligase in one package.

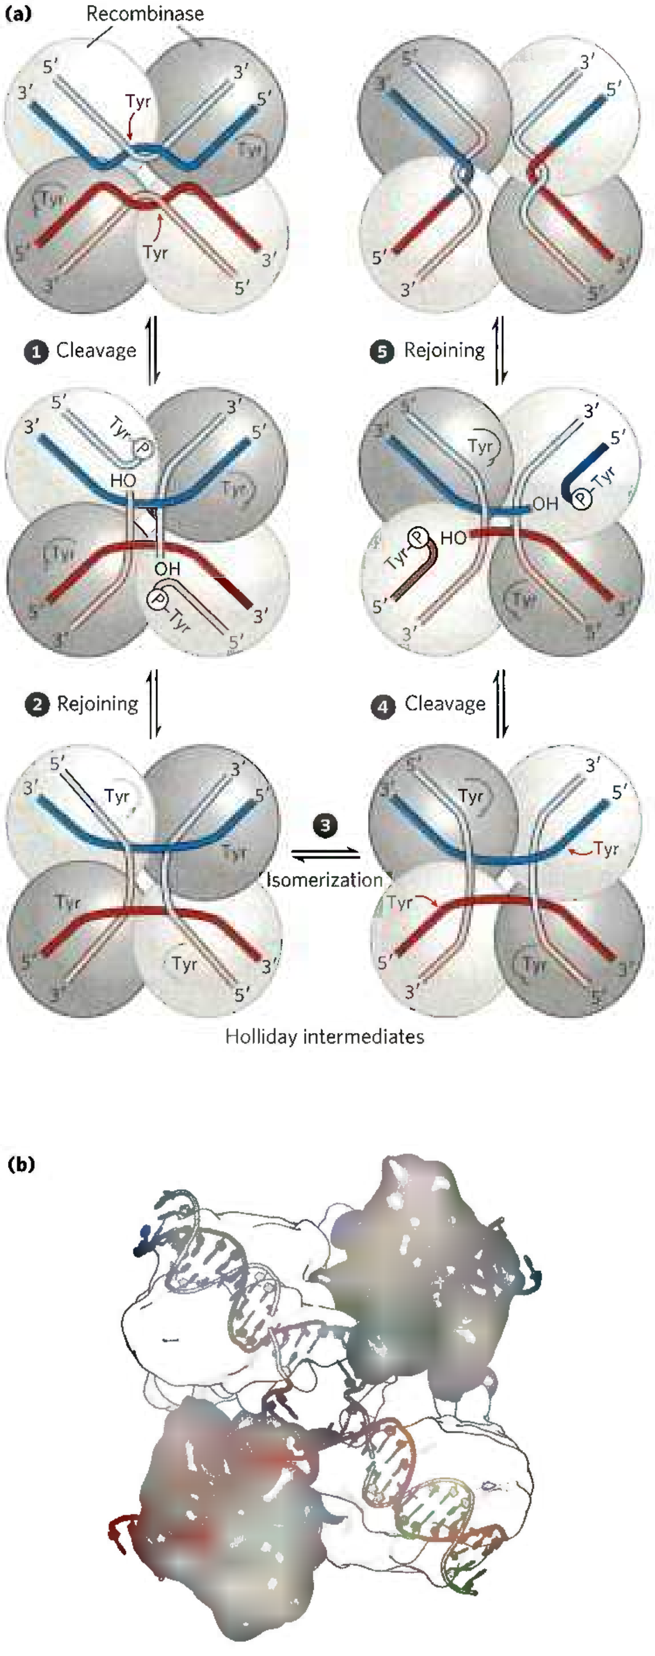

FIGURE 25-37 A site-specific recombination reaction. (a) The reaction shown here is for a common class of site-specific recombinases called integrase-class recombinases (named after bacteriophage λ integrase, the first recombinase characterized). These enzymes use Tyr residues as nucleophiles at the active site. The reaction is carried out within a tetramer of identical subunits. Recombinase subunits bind to a specific sequence, the recombination site. Two dimeric complexes, each bound to a single site in the DNA, come together to form the tetrameric complex shown here. ① One strand in each DNA is cleaved at particular points in the sequence. The nucleophile is the —OH group of an active-site Tyr residue, and the product of rejoining ② is a covalent phosphotyrosine link between protein and DNA. After isomerization ③, the cleaved strands join to new partners, producing a Holliday intermediate. Steps ④ and ⑤ complete the reaction by a process similar to the first two steps. The original sequence of the recombination site is regenerated after recombining the DNA flanking the site. These steps occur within a complex of multiple recombinase subunits that sometimes includes other proteins not shown here. (b) Surface contour model of a four-subunit integrase-class recombinase called the FLP recombinase, bound to a Holliday intermediate (shown with light blue and dark blue helix strands). The protein has been rendered transparent so that the bound DNA is visible. Another group of recombinases, called the resolvase/invertase family, use a Ser residue as nucleophile at the active site. [(b) Data from PDB ID 1P4E, P. A. Rice and Y. Chen, *J. Biol. Chem.* 278:24,800, 2003.]

The sequences of the recombination sites recognized by site-specific recombinases are partially asymmetric (nonpalindromic), and the two recombining sites align in the same orientation during the recombinase reaction. The outcome depends on the location and orientation of the recombination sites (**Fig. 25-38**). If the two sites are on the same DNA molecule, the reaction either inverts or deletes the intervening DNA, determined by whether the recombination sites have the opposite or the same orientation, respectively. If the sites are on different DNAs, the recombination is intermolecular; if one or both DNAs are circular, the result is an insertion. Some recombinase systems are highly specific for one of these reaction types and act only on sites with particular orientations.

Complete chromosomal replication can require site-specific recombination. Recombinational DNA repair of a circular bacterial chromosome, while essential, sometimes generates deleterious byproducts. The resolution of a Holliday intermediate at a replication fork by a nuclease such as RuvC, followed by completion of replication, can give rise to one of two products: the usual two monomeric chromosomes or a contiguous dimeric chromosome (**Fig. 25-39**). In the latter case, the covalently linked chromosomes cannot be segregated to daughter cells at cell division, and the dividing cells become "stuck." A specialized site-specific recombination system in *E. coli*, the XerCD system, converts the dimeric chromosomes to monomeric chromosomes so that cell division can proceed. The reaction is a site-specific deletion (Fig. 25-38b). **P4** This is another example of the close coordination between DNA recombination processes and other aspects of DNA metabolism.

Transposable Genetic Elements Move from One Location to Another

We now consider the third general type of recombination system: recombination that allows the movement of transposable elements, or **transposons**. These segments of DNA, found in virtually all cells, move, or "jump," from

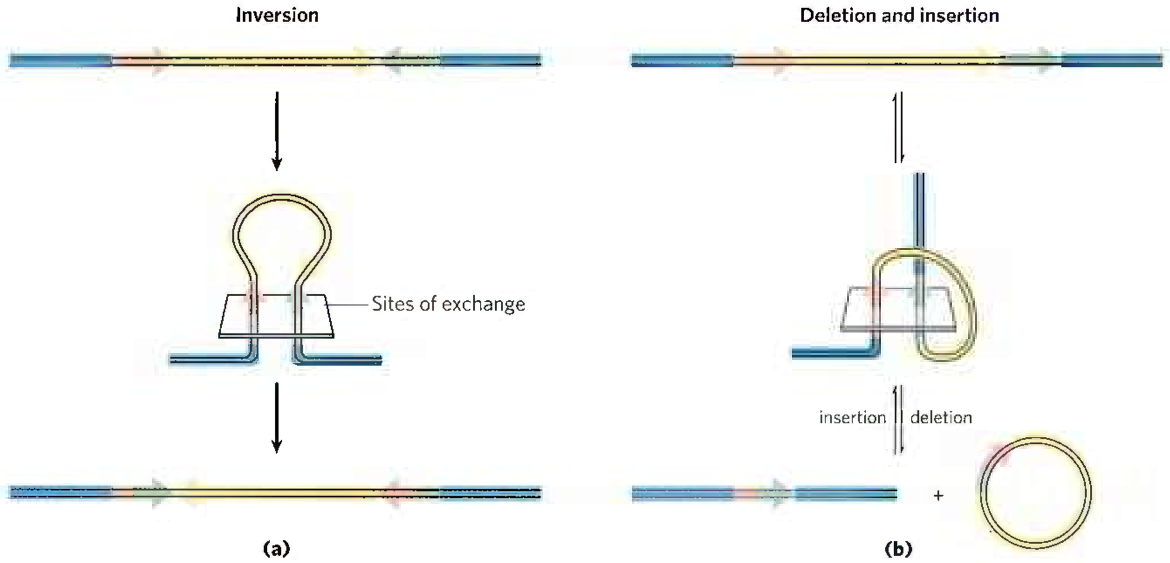

FIGURE 25-38 Effects of site-specific recombination. The outcome of site-specific recombination depends on the location and orientation of the recombination sites (red and green) in a double-stranded DNA molecule. Orientation here (shown by arrowheads) refers to the order of nucleotides in the recombination site, *not* the $5' \rightarrow 3'$ direction. (a) Recombination sites with opposite orientation in the same DNA molecule. The result is an inversion. (b) Recombination sites with the same orientation, either on one DNA molecule, producing a deletion, or on two DNA molecules, producing an insertion.

one place on a chromosome (the donor site) to another on the same or a different chromosome (the target site). DNA sequence homology is not usually required for this movement, called **transposition**; the new location is determined more or less randomly. Insertion of a transposon in an essential gene could kill the cell, so transposition is tightly regulated and usually very infrequent. Transposons are perhaps the simplest of molecular parasites, adapted to replicate passively within the chromosomes of host cells. In some cases they carry genes that are useful to the host cell, and thus exist in a kind of symbiosis with the host.

Bacteria have two classes of transposons. **Insertion sequences** (simple transposons) contain only the sequences required for transposition and the genes for the proteins (transposases) that promote the process. **Complex transposons** contain one or more genes in addition to those needed for transposition. These extra genes might, for example, confer resistance to antibiotics and thus enhance the survival chances of the host cell. The spread of antibiotic-resistance elements among disease-causing bacterial populations that is rendering some antibiotics ineffectual (p. 887) is mediated to a large degree by transposition. ■

Bacterial transposons vary in structure, but most have short repeated sequences at each end that serve as binding sites for the transposase. When transposition occurs, a short sequence at the target site (5 to 10 bp) is duplicated to form an additional short repeated sequence that flanks each end of the inserted transposon (**Fig. 25-40**). These duplicated segments result from the cutting mechanism used to insert a transposon into the DNA at a new location.

There are two general pathways for transposition in bacteria. In direct (or simple) transposition (**Fig. 25-41**,

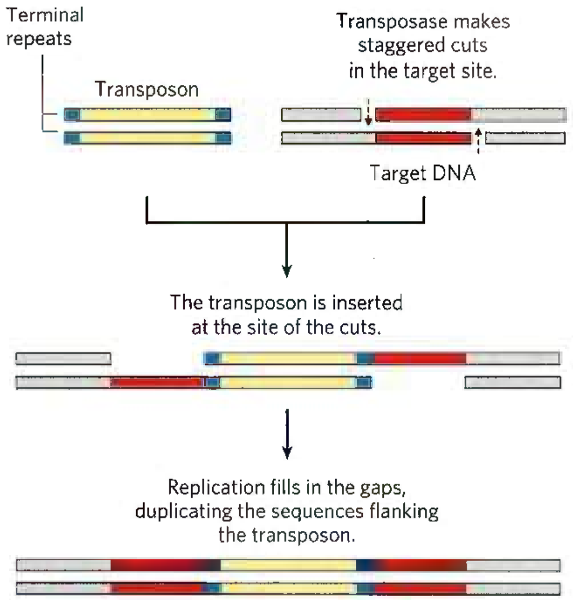
FIGURE 25-39 DNA deletion to undo a deleterious effect of recombinational DNA repair. The resolution of a Holliday intermediate during recombinational DNA repair (if cut at the points indicated by the red arrows) can generate a contiguous dimeric chromosome. A specialized site-specific recombinase in *E. coli*, XerCD, converts the dimer to monomers, allowing chromosome segregation and cell division to proceed.



Terminal repeats
Transposon
Transposase makes staggered cuts in the target site.
Target DNA
The transposon is inserted at the site of the cuts.
Replication fills in the gaps, duplicating the sequences flanking the transposon.

FIGURE 25-40 Duplication of the DNA sequence at a target site when a transposon is inserted. The sequences duplicated following transposon insertion are shown in red. These sequences are generally only a few base pairs long, so their size relative to that of a typical transposon is greatly exaggerated in this drawing.

left), cuts on each side of the transposon excise it, and the transposon moves to a new location. This leaves a double-strand break in the donor DNA that must be repaired. At the target site, a staggered cut is made (as in Fig. 25-40), the transposon is inserted into the break, and DNA replication fills in the gaps to duplicate the target-site sequence. In replicative transposition (Fig. 25-41, right), the entire transposon is replicated, leaving a copy behind at the donor location. A **cointegrate** is an intermediate in this process, consisting of the donor region covalently linked to DNA at the target site. Two complete copies of the transposon are present in the cointegrate, both having the same relative orientation in the DNA. In some well-characterized transposons, the cointegrate intermediate is converted to products by site-specific recombination, in which specialized recombinases promote the required deletion reaction.

Eukaryotes also have transposons, structurally similar to bacterial transposons, and some use similar transposition mechanisms. In other cases, however, the mechanism of transposition seems to involve an RNA intermediate. Evolution of these transposons is intertwined with the evolution of certain classes of RNA viruses. Both are described in the next chapter. As illustrated in Figure 9-25, nearly half of the human genome is made up of various types of transposable elements.

Immunoglobulin Genes Assemble by Recombination

Some DNA rearrangements are a programmed part of development in eukaryotic organisms. An important example is the generation of complete immunoglobulin genes from separate gene segments in vertebrate genomes.

FIGURE 25-41 Two general pathways for transposition: direct (simple) and replicative. ① The DNA is first cleaved on each side of the transposon, at the sites indicated by arrows. ② The liberated 3′-hydroxyl groups at the ends of the transposon act as nucleophiles in a direct attack on phosphodiester bonds in the target DNA. The target phosphodiester bonds are staggered (not directly across from each other) in the two DNA strands. ③ The transposon is now linked to the target DNA. In direct transposition (left), replication fills in gaps at each end to complete the process. In replicative transposition (right), the entire transposon is replicated to create a cointegrate intermediate. ④ The cointegrate is often resolved later, with the aid of a separate site-specific recombination system. The cleaved host DNA left behind after direct transposition is either repaired by DNA end joining or degraded (not shown); the latter outcome can be lethal to the organism.

A human (like other mammals) is capable of producing *millions* of different immunoglobulins (antibodies) with distinct binding specificities, even though the human genome contains only ~20,000 genes. Recombination allows an organism to produce an extraordinary diversity of antibodies from a limited DNA-coding capacity. Studies of the recombination mechanism reveal a close relationship to DNA transposition and suggest that this system for generating antibody diversity may have evolved from an ancient cellular invasion by transposons.

We can use the human genes that encode proteins of the immunoglobulin G (IgG) class to illustrate how antibody diversity is generated. Immunoglobulins consist of two heavy and two light polypeptide chains (see Fig. 5-20). Each chain has two regions: a variable region, with a sequence that differs greatly from one immunoglobulin to another, and a region that is virtually constant within a class of immunoglobulins. There are also two distinct families of light chains, kappa and lambda, which differ somewhat in the sequences of their constant regions. For all three types of polypeptide chains (heavy chain, and kappa and lambda light chains), diversity in the variable regions is generated by a similar mechanism. The genes for these polypeptides are divided into segments, and the genome contains clusters with multiple versions of each segment. The joining of one version of each gene segment creates a complete gene.

Figure 25-42 depicts the organization of the DNA encoding the kappa light chains of human IgG and shows how a mature kappa light chain is generated. In undifferentiated cells, the coding information for this polypeptide chain is separated into three segments. The V (variable) segment encodes the first 95 amino acid residues of the variable region, the J (joining) segment encodes the remaining 12 residues of the variable region, and the C segment encodes the constant region. The genome contains 40 different V segments, 5 different J segments, and 1 C segment.

As a stem cell in the bone marrow differentiates to form a mature B lymphocyte, one V segment and one J segment are brought together by a specialized recombination system (Fig. 25-42). During this programmed

FIGURE 25-42 Recombination of the V and J gene segments of the human IgG kappa light chain. At the top is shown the arrangement of IgG-coding sequences in a stem cell of the bone marrow. Recombination deletes the DNA between a particular V segment and a J segment. Transcription and RNA splicing, as described in Chapter 26, produces the light-chain polypeptide. The light chain can combine with any of 5,000 possible heavy chains to produce an antibody molecule.

DNA deletion, the intervening DNA is discarded. There are about 40 × 5 = 200 possible V–J combinations. The recombination process is not as precise as the site-specific recombination described earlier, so additional variation occurs in the sequence at the V–J junction. This increases the overall variation by a factor of at least 2.5, so the cells can generate about 2.5 × 200 = 500 different V–J combinations. The final joining of the V–J combination to the C region is accomplished by an RNA-splicing reaction after transcription, a process described in Chapter 26.

The recombination mechanism for joining the V and J segments is illustrated in **Figure 25-43**. Just beyond each V segment and just before each J segment lie recombination signal sequences (RSSs). These are bound by proteins called RAG1 and RAG2 (products of the *r*ecombination *a*ctivating *g*ene). The RAG proteins catalyze the formation of a double-strand break between the signal sequences and the V (or J) segments to be joined. The V and J segments are then joined with the aid of a second complex of proteins.

The genes for the heavy chains and the lambda light chains form by similar processes. Heavy chains have more gene segments than light chains, with more than 5,000 possible combinations. Because any heavy chain can combine with any light chain to generate an immunoglobulin, each human has at least 500 × 5,000 = 2.5 × 10^6 possible IgGs. And additional diversity is generated by high mutation rates (of unknown mechanism) in the V sequences during B-lymphocyte differentiation. Each mature B lymphocyte produces only one type of antibody, but the range of antibodies produced by the B lymphocytes of an individual organism is clearly enormous.

Did the immune system evolve in part from ancient transposons? The mechanism for generation of the double-strand breaks by RAG1 and RAG2 mirrors several reaction steps in transposition (Fig. 25-43). In addition, the deleted DNA, with its terminal RSSs, has a sequence structure found in most transposons. In the test tube, RAG1 and RAG2 can associate with this deleted DNA and insert it, transposonlike, into other DNA molecules (probably a rare reaction in B lymphocytes). Although we cannot know for certain, the properties of the immunoglobulin gene rearrangement system suggest an intriguing origin in which the distinction between host and parasite has become blurred by evolution.

FIGURE 25-43 Mechanism of immunoglobulin gene rearrangement. The RAG1 and RAG2 proteins bind to the recombination signal sequences (RSSs) and cleave one DNA strand between the RSS and the V (or J) segments to be joined. The liberated 3′ hydroxyl then acts as a nucleophile, attacking a phosphodiester bond in the other strand to create a double-strand break. The resulting hairpin bends on the V and J segments are cleaved, and the ends are covalently linked by a complex of proteins specialized for end-joining repair of double-strand breaks.

SUMMARY 25.3 *DNA Recombination*

- DNA sequences are rearranged in recombination reactions, usually in processes tightly coordinated with DNA replication or repair.
- Homologous genetic recombination can take place between any two DNA molecules that share sequence homology. In bacteria, recombination serves mainly as a DNA repair process, focused on reactivating stalled or collapsed replication forks or on the general repair of double-strand breaks.
- In eukaryotes, recombination is essential to ensure accurate chromosome segregation during the first meiotic cell division. It also helps to create genetic diversity in the resulting gametes.
- Nonhomologous end joining provides an alternative mechanism for the repair of double-strand breaks, especially in eukaryotic cells.
- Site-specific recombination occurs only at specific target sequences, and this process can also involve a Holliday intermediate. Recombinases cleave the DNA at specific points and ligate the strands to new partners. This type of recombination is found in virtually all cells, and its many functions include DNA integration and regulation of gene expression.
- In almost all cells, transposons use recombination to move within or between chromosomes.
- In vertebrates, a programmed recombination reaction related to transposition joins immunoglobulin gene segments to form immunoglobulin genes during B-lymphocyte differentiation.

KEY TERMS

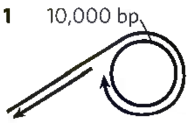
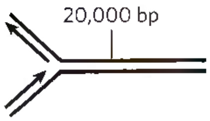
PROBLEMS

1. DNA Replication An investigator adds DNA polymerase III holoenzyme, DNA primase (DnaG), single-stranded DNA-binding protein (SSB), an ATP-dependent DNA ligase, and the replicative helicase (DnaB) to each of the DNA substrates shown, along with ATP and all four dNTPs. The length of DNA in the circle in structure **1** is 10,000 bp. The linear (unbranched) part of structure **2** is 20,000 bp long.

1



2



(a) If precursor (dNTP) concentrations are not limiting, Okazaki fragments are 2,000 nucleotides long, and replication proceeds at 1,000 nucleotides/s for 30 seconds, which DNA substrate will generate a longer replication product? **(b)** For structure **1**, draw the product of this 30 second replication. **(c)** Draw the expected product if DnaG were left out of the reaction. **(d)** Draw the expected product if DNA ligase were instead left out of the reaction.

2. Heavy Isotope Analysis of DNA Replication A researcher switches a culture of *E. coli* growing in a medium containing $^{15}NH_4Cl$ to a medium containing $^{14}NH_4Cl$ for three generations (an eightfold increase in population). What is the molar ratio of hybrid DNA (^{15}N–^{14}N) to light DNA (^{14}N–^{14}N) at this point?

3. Replication of the *E. coli* Chromosome The *E. coli* chromosome contains 4,641,652 bp.

(a) How many turns of the double helix must be unwound during replication of the *E. coli* chromosome?

(b) Using the data in this chapter, how long would it take to replicate the *E. coli* chromosome at 37 °C if two replication forks proceeded from the origin? Assume replication occurs at a rate of 1,000 bp/s. Under some conditions, *E. coli* cells can divide every 20 min. How might this be possible?

(c) In the replication of the *E. coli* chromosome, about how many Okazaki fragments would be formed? What factors are required to link together newly synthesized Okazaki fragments in the lagging strand?

4. Base Composition of DNAs Made from Single-Stranded Templates Predict the base composition of the total DNA synthesized by DNA polymerase on templates provided by an equimolar mixture of the two complementary strands of bacteriophage ϕX174 DNA (a circular DNA molecule). The base composition of one strand is A, 24.7%; G, 24.1%; C, 18.5%; and T, 32.7%. What assumption is necessary to answer this problem?

5. DNA Replication Kornberg and his colleagues incubated soluble extracts of *E. coli* with a mixture of dATP, dTTP, dGTP, and dCTP, all labeled with ^{32}P in the α-phosphate group. After a time, they treated the incubation mixture with trichloroacetic acid, which precipitates the DNA but not the nucleotide precursors. They then collected the precipitate and determined the extent of precursor incorporation into DNA from the amount of radioactivity present in the precipitate.

(a) If any one of the four nucleotide precursors were omitted from the incubation mixture, would radioactivity be found in the precipitate? Explain.

(b) Would ^{32}P be incorporated into the DNA if only dTTP were labeled? Explain.

(c) Would radioactivity be found in the precipitate if ^{32}P labeled the β phosphate or γ phosphate rather than the α phosphate of the deoxyribonucleotides? Explain.

6. The Chemistry of DNA Replication All DNA polymerases synthesize new DNA strands in the 5′→3′ direction. In some respects, replication of the antiparallel strands of duplex DNA would be simpler if there were also a second type of polymerase, one that synthesized DNA in the 3′→5′ direction. The two types of polymerase could, in principle, coordinate DNA synthesis without the complicated mechanics required for lagging strand replication. However, no such 3′→5′-synthesizing enzyme has been found. Suggest two possible mechanisms for 3′→5′ DNA synthesis. Pyrophosphate should be one product of both proposed reactions. Could one or both mechanisms be supported in a cell? Why or why not? (Hint: You may suggest the use of DNA precursors not actually present in extant cells.)

7. Activities of DNA Polymerases You are characterizing a new DNA polymerase. When you incubate the enzyme with ^{32}P-labeled DNA and no dNTPs, you observe the release of $[^{32}P]$dNMPs. The addition of unlabeled dNTPs prevents this release. Explain the reactions that most likely underlie these observations. What would you expect to observe if you added pyrophosphate instead of dNTPs?

8. Leading and Lagging Strands Prepare a table that lists the names and compares the functions of the precursors, enzymes, and other proteins needed to make the leading strand versus the lagging strand during DNA replication in *E. coli*.

9. Function of DNA Ligase Some *E. coli* mutants contain defective DNA ligase. When researchers expose these mutants to ^{3}H-labeled thymine and then sediment the DNA produced on an alkaline sucrose density gradient, two radioactive bands appear. One corresponds to a high molecular weight fraction, the other to a low molecular weight fraction. Explain.

10. Fidelity of Replication of DNA What factors promote the fidelity of replication during synthesis of the leading strand of DNA? Would you expect the lagging strand to be made with the same fidelity? Give reasons for your answers.

11. Importance of DNA Topoisomerases in DNA Replication DNA unwinding, such as that occurring in replication, affects the superhelical density of DNA. In the absence of topoisomerases, the DNA would become overwound ahead of a replication fork as the DNA is unwound behind it. A bacterial replication fork will stall when the superhelical density (σ) of the DNA ahead of the fork reaches +0.14 (see Chapter 24).

An investigator initiates bidirectional replication at the origin of a 6,000 bp plasmid in vitro, in the absence of topoisomerases. The plasmid initially has a σ of -0.06. How many base pairs will be unwound and replicated by each replication fork before the forks stall? Assume that both forks travel at the same rate and that each includes all components necessary for elongation except topoisomerase.

12. The Ames Test In a nutrient medium that lacks histidine, a thin layer of agar containing ~10^9 *Salmonella typhimurium* histidine auxotrophs (mutant cells that require histidine to survive) produces ~13 colonies over a two-day incubation period at 37 °C (see Fig. 25-19). How do these colonies arise in the absence of histidine? When investigators repeat the experiment in the presence of 0.4 μg of 2-aminoanthracene, the number of colonies produced over two days exceeds 10,000. What does this indicate about 2-aminoanthracene? What can you surmise about its carcinogenicity?

13. DNA Repair Mechanisms Vertebrate and plant cells often methylate cytosine in DNA to form 5-methylcytosine (see Fig. 8-5a). In these same cells, a specialized repair system recognizes G–T mismatches and repairs them to G≡C base pairs. How might this repair system be advantageous to the cell? (Explain in terms of the presence of 5-methylcytosine in the DNA.)

14. The Energetic Cost of Mismatch Repair In an *E. coli* cell, DNA polymerase III makes a rare error and inserts a G opposite an A residue at a position 650 bp away from the nearest GATC sequence. The mismatch repair system accurately repairs the mismatch. How many phosphodiester bonds derived from deoxynucleotides (dNTPs) does this repair expend? This process also uses ATP molecules. Which enzyme(s) consume the ATP?

15. DNA Repair in People with Xeroderma Pigmentosum The condition known as xeroderma pigmentosum (XP) arises from mutations in at least seven different human genes (see Box 25-1). The deficiencies are generally in genes encoding enzymes involved in some part of the pathway for human nucleotide-excision repair. The various types of XP are denoted A through G (XPA, XPB, etc.), with a few additional variants lumped under the label XPV.

Investigators irradiate cultures of fibroblasts from healthy individuals and from patients with XPG with ultraviolet light. After isolating and denaturing the DNA, they characterize the resulting single-stranded DNA by analytical ultracentrifugation.

(a) Samples from the normal fibroblasts show a significant reduction in the average molecular weight of the single-stranded DNA after irradiation, but samples from the XPG fibroblasts show no such reduction. Why might this be?

(b) If you assume that a nucleotide-excision repair system is operative in fibroblasts, which step might be defective in the cells from the patients with XPG? Explain.

16. DNA Repair and Cancer Many pharmaceuticals used for tumor chemotherapy are DNA damaging agents. What is the rationale behind actively damaging DNA to address tumors? Why do such treatments often have a greater effect on a tumor than on healthy tissue?

17. Direct Repair Cells normally repair the lesion O^6-meG by directly transferring the methyl group to the protein O^6-methylguanine-DNA methyltransferase. For the nucleotide sequence AAC(O^6-meG)TGCAC, with a damaged (methylated) G residue, what would be the sequence of both strands of double-stranded DNA resulting from replication in each of the situations listed?

(a) Replication occurs before repair.

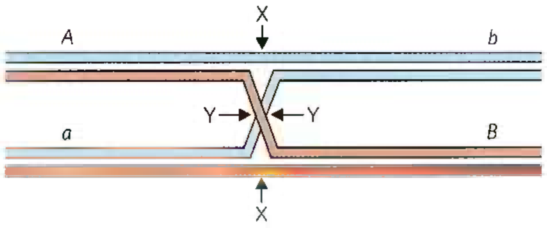
(b) Replication occurs after repair.

(c) Two rounds of replication occur, followed by repair.

18. Strand Invasion in Recombination A key step in many homologous recombination reactions is strand invasion (see step ② in Fig. 25-29). In almost every case, strand invasion proceeds with a single strand that has a free 3′ end rather than a 5′ end. What DNA metabolic advantage is inherent with the use of a free 3′ end for strand invasion?

19. Holliday Intermediates How does the formation of Holliday intermediates in homologous genetic recombination differ from their formation in site-specific recombination?

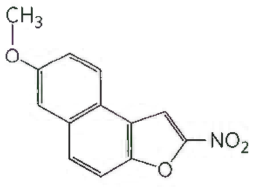
20. Cleavage of Holliday Intermediates A Holliday intermediate forms between two homologous chromosomes, at a point between genes *A* and *B*, as shown. The chromosomes have different alleles of the two genes (*A* and *a*, *B* and *b*). Where would the Holliday intermediate have to be cleaved (points X and/or Y) to generate a chromosome that would carry **(a)** an *Ab* genotype or **(b)** an *ab* genotype?



21. A Connection between Replication and Site-Specific Recombination Most wild strains of *S. cerevisiae* have multiple copies of the circular DNA plasmid 2μ (named for its contour length of about 2 μm), which has ~6,300 bp. For its replication, the plasmid uses the host replication system, under the same strict control as the host cell chromosomes, replicating only once per cell cycle. Replication of the plasmid is bidirectional, with both replication forks initiating at a single, well-defined origin. However, one replication cycle of a 2μ plasmid can result in more than two copies of the plasmid, allowing amplification of the plasmid copy number (number of plasmid copies per cell) whenever plasmid segregation at cell division leaves one daughter cell with fewer than the normal complement of plasmid copies. Amplification requires a site-specific recombination system encoded by the plasmid, which serves to invert one part of the plasmid relative to the other. Explain how a site-specific inversion event could result in amplification of the plasmid copy number. (Hint: Consider the situation when replication forks have duplicated one recombination site but not the other.)

DATA ANALYSIS PROBLEM

22. Mutagenesis in *Escherichia coli* Many mutagenic compounds act by alkylating the bases in DNA. The alkylating agent R7000 (7-methoxy-2-nitronaphtho[2,1-*b*]furan) is an extremely potent mutagen.

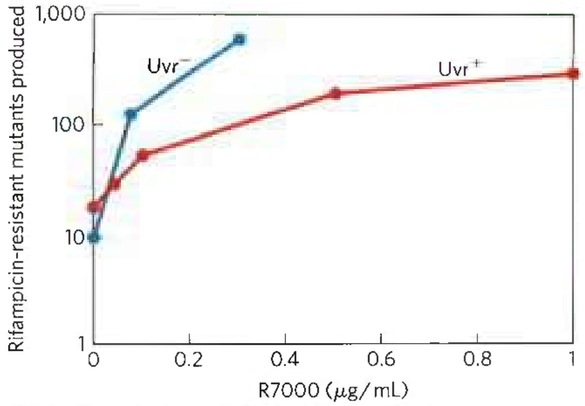


R7000

In vivo, R7000 is activated by the enzyme nitroreductase, and this more reactive form covalently attaches to DNA—primarily, but not exclusively, to G≡C base pairs.

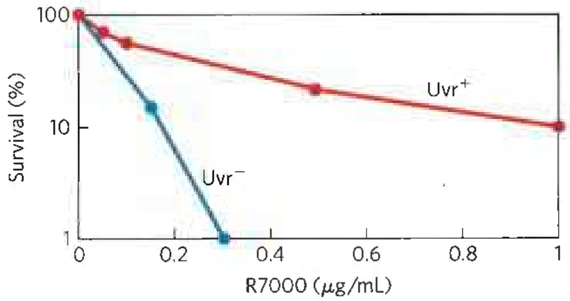
In a 1996 study, Quillardet, Touati, and Hofnung explored the mechanisms by which R7000 causes mutations in *E. coli*. They compared the genotoxic activity of R7000 in two strains of *E. coli*: the wild-type (Uvr$^+$) and mutants lacking *uvrA* activity (Uvr$^-$). They first measured rates of mutagenesis. Rifampicin is an inhibitor of RNA polymerase. In its presence, cells will not grow unless certain mutations occur in the gene encoding RNA polymerase; the appearance of rifampicin-resistant colonies thus provides a useful measure of mutagenesis rates.

The investigators determined the effects of different concentrations of R7000. Their results are shown in the following graph:



(a) Why are some mutants produced even when no R7000 is present?

Quillardet and colleagues also measured the survival rate of bacteria treated with different concentrations of R7000, with the following results:



(b) Explain how treatment with R7000 is lethal to cells.

(c) Explain the differences in the mutagenesis curves and in the survival curves for the two types of bacteria, Uvr$^+$ and Uvr$^-$, as shown in the graphs.

The researchers went on to measure the amount of R7000 covalently attached to the DNA in Uvr$^+$ and Uvr$^-$ *E. coli*. They incubated bacteria with [^{3}H]R7000 for 10 or 70 minutes, extracted the DNA, and measured its ^{3}H content in counts per minute (cpm) per microgram of DNA.

	^{3}H in DNA (cpm/μg)	
Time (min)	**Uvr$^+$**	**Uvr$^-$**
10	76	159
70	69	228

(d) Explain why the amount of ^{3}H drops over time in the Uvr$^+$ strain and rises over time in the Uvr$^-$ strain.

Quillardet and colleagues then examined the particular DNA sequence changes caused by R7000 in the Uvr$^+$ and Uvr$^-$ bacteria. For this, they used six different strains of *E. coli*, each with a different point mutation in the *lacZ* gene, which encodes β-galactosidase. Cells with any of these mutations have a nonfunctional β-galactosidase and are unable to metabolize lactose (i.e., a Lac$^-$ phenotype). Each type of point mutation required a specific reverse mutation to restore *lacZ* gene function and Lac$^+$ phenotype. By plating cells on a medium containing lactose as the sole carbon source, the researchers selected for these reverse-mutated, Lac$^+$ cells. And by counting the number of Lac$^+$ cells following mutagenesis of a particular strain, they could measure the frequency of each type of mutation.

First, they looked at the mutation spectrum in Uvr$^-$ cells. The following table shows the results for the six strains, CC101 through CC106 (with the point mutation required to produce Lac$^+$ cells indicated in parentheses).

Number of Lac$^+$ cells (average ± SD)

R7000 (μg/mL)	CC101 (A=T to C≡G)	CC102 (G≡C to A=T)	CC103 (G≡C to C≡G)	CC104 (G≡C to T=A)	CC105 (A=T to T=A)	CC106 (A=T to G≡C)
0	6 ± 3	11 ± 9	2 ± 1	5 ± 3	2 ± 1	1 ± 1
0.075	24 ± 19	34 ± 3	8 ± 4	82 ± 23	40 ± 14	4 ± 2
0.15	24 ± 4	26 ± 2	9 ± 5	180 ± 71	130 ± 50	3 ± 2

(e) Which types of mutation show significant increases above the background rate due to treatment with R7000? Provide a plausible explanation for why some have higher frequencies than others.

(f) Can all of the mutations you listed in (e) be explained as resulting from covalent attachment of R7000 to a G≡C base pair? Explain your reasoning.

(g) Figure 25-26b shows how methylation of guanine residues can lead to a G≡C to A=T mutation. Using a similar pathway, show how an R7000–G adduct could lead to the G≡C to A=T or T=A mutations shown above. Which base pairs with the R7000–G adduct?

The results for the Uvr$^+$ bacteria are shown in the following table.

Number of Lac$^+$ cells (average ± SD)

R7000 (μg/mL)	CC101 (A=T to C≡G)	CC102 (G≡C to A=T)	CC103 (G≡C to C≡G)	CC104 (G≡C to T=A)	CC105 (A=T to T=A)	CC106 (A=T to G≡C)
0	2 ± 2	10 ± 9	3 ± 3	4 ± 2	6 ± 1	0.5 ± 1
1	7 ± 6	21 ± 9	8 ± 3	23 ± 15	13 ± 1	1 ± 1
5	4 ± 3	15 ± 7	22 ± 2	68 ± 25	67 ± 14	1 ± 1

(h) Do these results show that all mutation types are repaired with equal fidelity? Provide a plausible explanation for your answer.

RNA METABOLISM

26.1 DNA-Dependent Synthesis of RNA *961*

26.2 RNA Processing *972*

26.3 RNA-Dependent Synthesis of RNA and DNA *988*

26.4 Catalytic RNAs and the RNA World Hypothesis *995*

Expression of the information in a gene generally involves production of an RNA molecule transcribed from a DNA template. Strands of RNA and DNA may seem similar at first glance, differing only in that RNA has a hydroxyl group at the 2′ position of the aldopentose, and uracil usually replaces thymine. However, unlike DNA, most RNAs carry out their functions as single strands, strands that fold back on themselves and have the potential for much greater structural diversity than DNA (Chapter 8). RNA is thus suited to a variety of cellular functions.

RNA is the only macromolecule known to have a role both in the storage and transmission of information and in catalysis, which has led to much speculation about its possible role as an essential chemical intermediate in the development of life on this planet. The discovery of catalytic RNAs, or **ribozymes**, has changed the very definition of an enzyme, extending it beyond the domain of proteins. Proteins nevertheless remain essential to RNA and its cellular functions. In the biosphere of today, all nucleic acids, including RNAs, are complexed with proteins. In the case of RNA, these complexes are called **ribonucleoproteins** or **RNPs**. Some of these RNPs are quite elaborate, and RNA can assume both structural and catalytic roles within complicated biochemical machines.

All RNA molecules except the RNA genomes of certain viruses are derived from information permanently stored in DNA. During **transcription**, an enzyme system converts the genetic information in a segment of double-stranded DNA into an RNA strand with a base sequence complementary to one of the DNA strands. Four major kinds of RNA are produced. **Messenger RNAs (mRNAs)** encode the amino acid sequence of one or more polypeptides specified by a gene or set of genes. **Transfer RNAs (tRNAs)** read the information encoded in the mRNA and transfer the appropriate amino acid to a growing polypeptide chain during protein synthesis. **Ribosomal RNAs (rRNAs)** are constituents of ribosomes, the intricate cellular machines that synthesize proteins. **Noncoding RNAs (ncRNAs)** have a variety of catalytic, structural, and regulatory functions.

During replication the entire chromosome is usually copied, but transcription is more selective. Only particular genes or groups of genes are transcribed at any one time, and some portions of the DNA genome are never transcribed. The cell restricts the expression of genetic information to the formation of gene products needed at any particular moment. The sum of all the RNA molecules produced in a cell under a given set of conditions is called the cellular **transcriptome**. Given the relatively small fraction of the human genome devoted to protein-coding genes (about 2%), we might expect that only a small part of the human genome is transcribed. This is not the case. Transcriptome analyses have revealed that approximately 76% of the human genome is transcribed into RNA. The products are predominantly not mRNAs but rather ncRNAs. Many ncRNAs are involved in regulating gene expression by interaction with other RNAs, genomic DNA, or proteins. However, the rapid pace of their discovery has forced us to realize that we do not yet know the function of the majority of our genomic ncRNA transcripts.

In this chapter we examine the synthesis of RNA on a DNA template and the postsynthetic processing, location, and turnover of RNA molecules. In doing so, we encounter many of the specialized functions of RNA, including catalytic functions. We also describe systems in which RNA is the template and DNA the product, rather than vice versa. The information pathways thus come full circle and reveal that template-dependent nucleic acid synthesis has standard rules, regardless of the nature of template or product (RNA or DNA). This examination of the biological interconversion of DNA and RNA as information carriers leads inevitably to a discussion of the evolutionary origin of biological information and processing. We will be guided by four principles.

P1 **RNA is synthesized by RNA polymerases using DNA templates and ribonucleoside 5′-triphosphates.** RNA is made in the 5′→3′ direction and complementary to the template DNA strand. Transcription is highly regulated and initiates by recruitment of the transcription machinery to gene promoters. Although bacterial and eukaryotic polymerases share many conserved features, the transcriptional machinery and its regulation are much more complex in eukaryotes.

P2 **Many RNAs must be modified and processed to become functional.** RNAs can be modified by nucleases, by excision of certain RNA segments, and/or by chemical modification of the RNA nucleotides. In humans, nearly all mRNAs are 5′ capped, spliced, and polyadenylated before being exported from the nucleus for translation in the cytoplasm.

P3 **RNA can be used as a template for synthesis of DNA by reverse transcriptases.** RNA carries genetic information that can be reverse transcribed into DNA. Retroviruses, such as HIV or those responsible for some cancers, must convert their RNA genomes into DNA by reverse transcription. Reverse transcription by telomerase is also responsible for producing the telomeres that protect the DNA found at the ends of eukaryotic chromosomes.

P4 **RNA can act as both a catalyst and carrier of genetic information.** Ribozymes can catalyze chemical transformations using many of the same strategies as protein-based enzymes. The dual capacity of RNA as both a carrier of genetic information and a catalyst is support for the RNA world hypothesis for the evolution of life on Earth.

26.1 DNA-Dependent Synthesis of RNA

Our discussion of RNA synthesis begins with a comparison between transcription and DNA replication (Chapter 25). Transcription resembles replication in its fundamental chemical mechanism, its polarity (direction of synthesis), and its use of a template. And like replication, transcription has initiation, elongation, and termination phases. Transcription differs from replication in that it does not require a primer and, generally, involves only limited segments of a DNA molecule. Additionally, only one DNA strand serves as a template for a particular RNA molecule.

RNA Is Synthesized by RNA Polymerases

The discovery of DNA polymerase and its dependence on a DNA template spurred a search for an enzyme that synthesizes RNA complementary to a DNA strand. By 1960, four research groups had independently detected an enzyme in cellular extracts that could form an RNA polymer from ribonucleoside 5′-triphosphates. Subsequent work on the purified *Escherichia coli* RNA polymerase helped to define the fundamental properties of transcription (**Fig. 26-1**). P1 **DNA-dependent RNA polymerase** requires, in addition to a DNA template, all four ribonucleoside 5′-triphosphates (ATP, GTP, UTP, and CTP) as precursors of the nucleotide units of RNA, as well as Mg^{2+}. The chemistry and mechanism of RNA synthesis closely resemble those used by DNA polymerases (see Fig. 25-3). RNA polymerase elongates an RNA strand by adding ribonucleotide units to the 3′-hydroxyl end, building RNA in the 5′→3′ direction. The 3′-hydroxyl group acts as a nucleophile, attacking the α phosphate of the incoming ribonucleoside triphosphate (Fig. 26-1a) and releasing pyrophosphate. The overall reaction is

$$\underset{\text{RNA}}{(\text{NMP})_n} + \text{NTP} \longrightarrow \underset{\text{Lengthened RNA}}{(\text{NMP})_{n+1}} + \text{PP}_\text{i}$$

RNA polymerase requires DNA for activity and is most active when bound to a double-stranded DNA. As noted above, only one of the two DNA strands serves as a template. The template DNA strand is copied in the 3′→5′ direction (antiparallel to the new RNA strand), just as in DNA replication. Each nucleotide in the newly formed RNA is selected by Watson-Crick base-pairing interactions: U residues are inserted in the RNA to pair with A residues in the DNA template, G residues are inserted to pair with C residues, and so on. Base-pair geometry (see Fig. 25-5) may also play a role in base selection.

Unlike DNA polymerase, RNA polymerase does not require a primer to initiate synthesis. Initiation occurs when RNA polymerase binds at specific DNA sequences called promoters (described below). The 5′-triphosphate group of the first residue in a nascent (newly formed) RNA molecule is not cleaved to release PP_i, but instead remains intact and functions in eukaryotes as a substrate for the RNA-capping machinery (see Fig. 26-13). During the elongation phase of transcription, the growing end of the new RNA strand base-pairs temporarily with the DNA template to form a short hybrid RNA-DNA double helix, about 8 bp long (Fig. 26-1b). The RNA in this hybrid duplex "peels off" shortly after its formation, and the DNA duplex re-forms.

To enable RNA polymerase to synthesize an RNA strand complementary to one of the DNA strands, the DNA duplex must unwind over a short distance, forming a transcription "bubble." During transcription, the *E. coli* RNA polymerase generally keeps about 17 bp unwound. The 8 bp RNA-DNA hybrid occurs in this unwound region. Elongation of a transcript by *E. coli* RNA polymerase proceeds at a rate of 50 to 90 nucleotides/s. Because DNA is a helix, movement of a transcription bubble requires considerable strand rotation of the nucleic acid molecules. DNA strand rotation is restricted in most DNAs by DNA-binding proteins and other structural barriers. As a result, a moving RNA polymerase generates

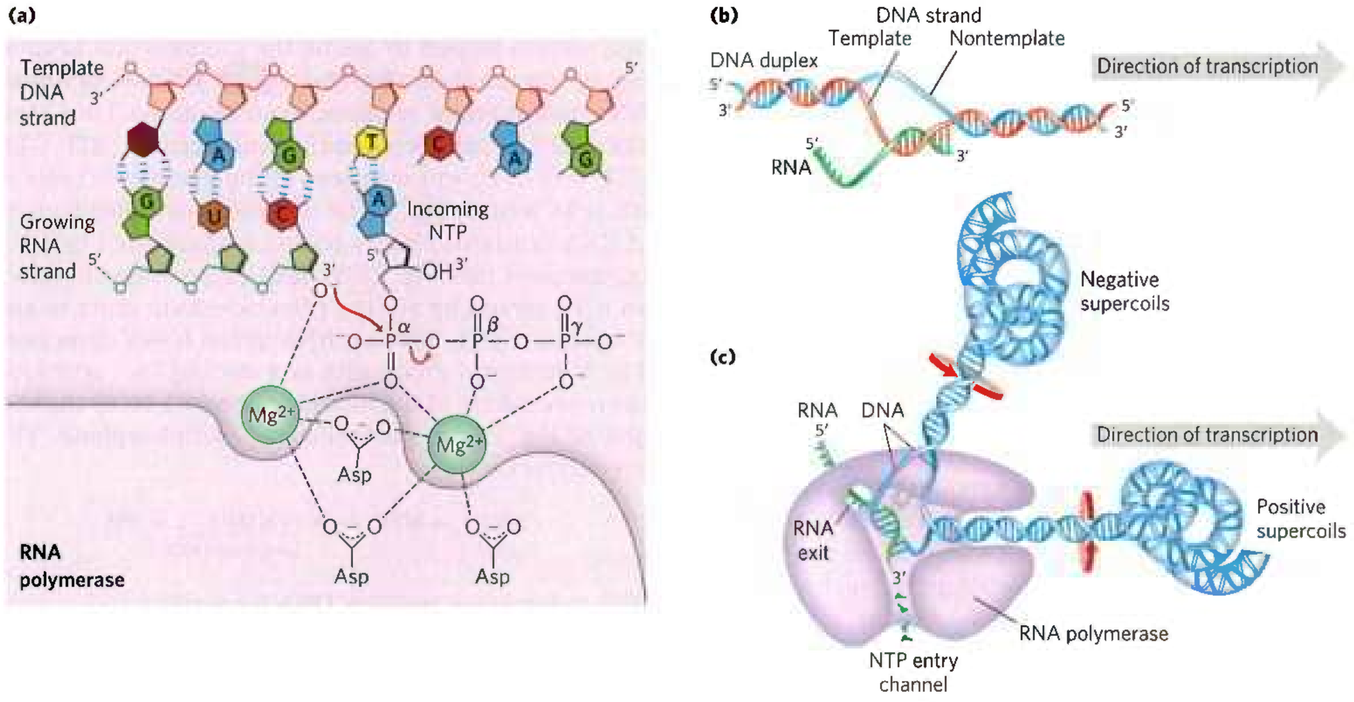

FIGURE 26-1 Transcription by RNA polymerase in *E. coli*. For synthesis of an RNA strand complementary to one of two DNA strands in a double helix, the DNA is transiently unwound. (a) Catalytic mechanism of RNA synthesis by RNA polymerase. Notice that this is essentially the same mechanism used by DNA polymerases. The reaction involves two Mg^{2+} ions coordinated to the phosphate groups of the incoming nucleoside triphosphates (NTPs) and to three Asp residues, which are highly conserved in the RNA polymerases of all species. One Mg^{2+} ion facilitates attack by the 3′-hydroxyl group on the α phosphate of the NTP; the other Mg^{2+} ion facilitates displacement of the pyrophosphate. Both metal ions stabilize the pentacovalent transition state. (b) About 17 bp of DNA are unwound at any given time. RNA polymerase and the transcription bubble move from left to right along the DNA as shown, facilitating RNA synthesis. The DNA is unwound ahead and rewound behind as RNA is transcribed. As the DNA is rewound, the RNA-DNA hybrid is displaced and the RNA strand is extruded. (c) Movement of an RNA polymerase along DNA tends to create positive supercoils (overwound DNA) ahead of the transcription bubble and negative supercoils (underwound DNA) behind it. The RNA polymerase is in close contact with the DNA ahead of the transcription bubble as well as with the separated DNA strands and the RNA within and immediately behind the bubble. A channel in the protein funnels new NTPs to the polymerase active site. The polymerase footprint encompasses about 35 bp of DNA during elongation.

waves of positive supercoils ahead of the transcription bubble and negative supercoils behind (Fig. 26-1c). This has been observed both in vitro and in vivo (in bacteria). In the cell, the topological problems caused by transcription are relieved through the action of topoisomerases (Chapter 24).

KEY CONVENTION The two complementary DNA strands have different roles in transcription. The strand that serves as template for RNA synthesis is called the **template strand.** The DNA strand complementary to the template, the **nontemplate strand,** or **coding strand,** is identical in base sequence to the RNA transcribed from the gene, with U in the RNA in place of T in the DNA (Fig. 26-2). The coding strand for a particular gene may be located in either strand of a given chromosome (as shown in Fig. 26-3 for a virus). By convention, the regulatory sequences that control transcription (described later in this chapter) are designated by the sequences in the coding strand. ■

The DNA-dependent RNA polymerase of *E. coli* is a large, complex enzyme with five core subunits ($\alpha_2\beta\beta'\omega$; M_r 390,000) and a sixth subunit, one of a group designated

(5′) C G C T A T A G C G T T T (3′)	DNA nontemplate (coding) strand
(3′) G C G A T A T C G C A A A (5′)	DNA template strand
(5′) C G C U A U A G C G U U U (3′)	RNA transcript

FIGURE 26-2 Template and nontemplate (coding) DNA strands. The two complementary strands of DNA are defined by their function in transcription. The RNA transcript is synthesized on the template strand and is identical in sequence (with U in place of T) to the nontemplate strand, or coding strand.

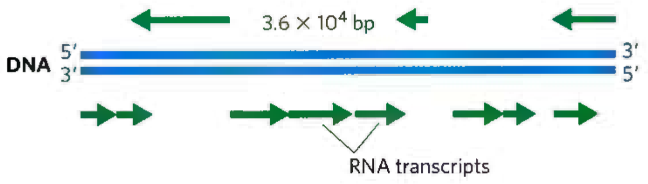

FIGURE 26-3 Organization of coding information in the adenovirus genome. The genetic information of the adenovirus genome is encoded by a double-stranded DNA molecule of 36,000 bp, both strands of which encode proteins. The information for most proteins is encoded by (that is, identical to) the top strand — by convention, the strand is oriented 5′ to 3′ from left to right. The bottom strand acts as template for these transcripts. However, a few proteins are encoded by the bottom strand, which is transcribed in the opposite direction (and uses the top strand as template).

σ, with variants designated by size (molecular weight). The σ subunit binds transiently to the core and directs the enzyme to specific binding sites on the DNA (described below). These six subunits constitute the RNA polymerase holoenzyme (**Fig. 26-4**). The RNA polymerase holoenzyme of *E. coli* thus exists in several forms, depending on the type of σ subunit. The most common subunit is σ^{70} (M_r 70,000), and the upcoming discussion focuses on the corresponding RNA polymerase holoenzyme.

RNA polymerases lack a separate proofreading $3' \rightarrow 5'$ exonuclease active site (such as that of many DNA polymerases), and the error rate for transcription is higher than that for chromosomal DNA replication—approximately one error for every 10^4 to 10^5 ribonucleotides incorporated into RNA. Because many copies of an RNA are generally produced from a single gene, and nearly all RNAs are eventually degraded and replaced, a mistake in an RNA molecule is of less consequence to the cell than a mistake in the permanent information stored in DNA. Many RNA polymerases, including bacterial RNA polymerase and the eukaryotic RNA polymerase II (discussed below), do pause when a mispaired base is added during transcription, and they can remove mismatched nucleotides from the 3′ end of a transcript by direct reversal of the polymerase reaction. But we do not yet know whether this activity is a true proofreading function and to what extent it may contribute to the fidelity of transcription.

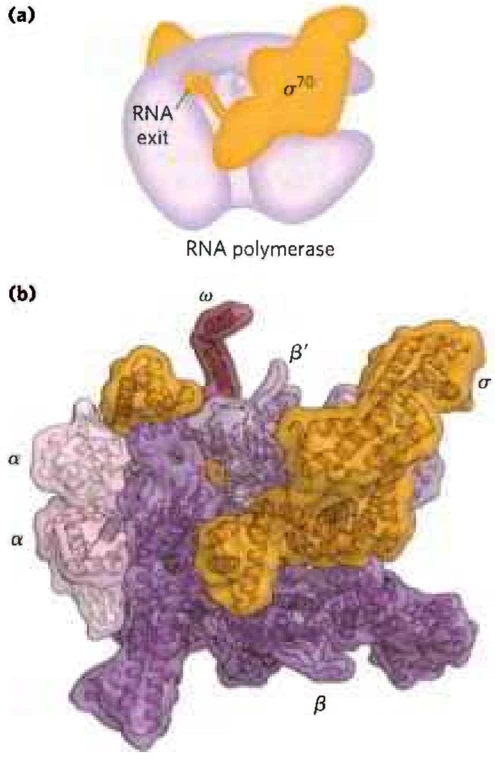

FIGURE 26-4 Structure of the σ^{70} RNA polymerase holoenzyme of *E. coli*. (a) The several subunits of the bacterial RNA polymerase give the enzyme the shape of a crab claw (purple). The σ^{70} subunit rests on top of the crab claw and threads through the RNA exit channel. (b) In this crystal structure of the RNA polymerase holoenzyme, each of the six subunits ($\alpha_2\beta\beta'\omega$ and σ^{70}) can be identified. The pincers of the crab claw are formed by the β and β' subunits. [Data from PDB ID 4MEY, D. Degen et al., *eLife* 3:e02451, 2014.]

RNA Synthesis Begins at Promoters

Initiation of RNA synthesis at random points in a DNA molecule would be an extraordinarily wasteful process. **P1** Instead, an RNA polymerase binds to specific sequences in the DNA called **promoters**, which direct the transcription of adjacent segments of DNA (genes). The sequences where RNA polymerases bind are variable, and much research has focused on identifying the particular sequences that are critical to promoter function.

In *E. coli*, RNA polymerase binding occurs within a region stretching from about 70 bp before the transcription start site to about 30 bp beyond it. By convention, the DNA base pairs that correspond to the beginning of an RNA molecule are given positive numbers, and those preceding the RNA start site are given negative numbers. The promoter region thus extends between positions −70 and +30. Analyses and comparisons of the most common class of bacterial promoters (those recognized by an RNA polymerase holoenzyme containing σ^{70}) have revealed consensus sequences centered about positions −10 and −35 (**Fig. 26-5a**). Although the sequences are not identical for all bacterial promoters in this class, certain nucleotides that are particularly common at each position form a **consensus sequence**. The consensus sequence at the −10 region is (5′)TATAAT(3′); at the −35 region it is (5′)TTGACA(3′). A third AT-rich recognition element, called the UP (upstream promoter) element, occurs between positions −40 and −60 in the promoters of certain highly expressed genes. The UP element is bound by the α subunit of RNA polymerase. The efficiency with which an RNA polymerase containing σ^{70} binds to a promoter and initiates transcription is determined in large measure by these sequences, the spacing between them, and their distance from the transcription start site. A change in only one base pair in the promoter can decrease the rate of binding by several orders of magnitude. The promoter sequence thus establishes a basal level of expression that can vary greatly from one *E. coli* gene to the next. The x-ray crystal structure of the σ^{70} RNA polymerase holoenzyme bound to its promoter shows how the σ factor recognizes both the RNA polymerase and the −10 and −35 regions by introducing a large bend in the DNA (Fig. 26-5b). Information about these interactions can also be obtained using the method illustrated in **Box 26-1**.

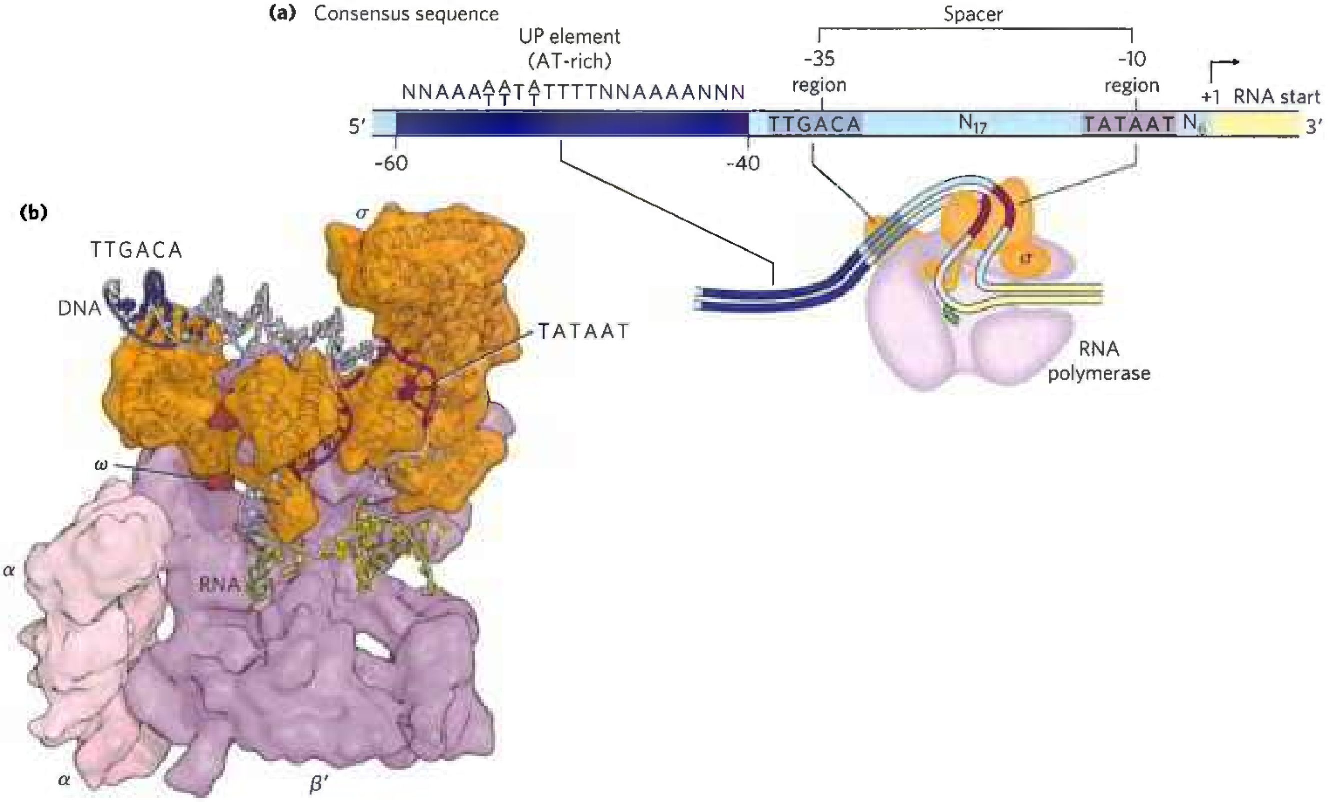

FIGURE 26-5 Promoter recognition by RNA polymerase holoenzymes containing σ^{70}. (a) The nontemplate strand of the consensus sequence for *E. coli* promoters recognized by σ^{70} is shown, read in the 5′→3′ direction, as is the convention for representations of this kind. The sequences differ from one promoter to the next, but comparisons of many promoters reveal similarities, particularly in the −10 and −35 regions. The sequence element UP, not present in all *E. coli* promoters, generally occurs in the region between −40 and −60 and strongly stimulates transcription at the promoters that contain them. Spacer regions contain slightly variable numbers of nucleotides (N). Only the first nucleotide coding the RNA transcript (at position +1) is shown. (b) This x-ray crystallographic structure of the *E. coli* holoenzyme bound to a promoter shows that the σ^{70} subunit introduces a sharp bend in the DNA template, allowing it to simultaneously contact the −35 and −10 regions as well as the RNA polymerase core. In this view the *β* subunit was omitted to allow the path of the DNA through the polymerase to be more easily seen. Due to the low resolution of the structure (5.5 Å) not all of the DNA backbone could be modeled, and these unmodeled regions are missing from the DNA shown in the figure. A cartoon schematic of the structure is also shown below (a), aligned with consensus promoter elements. [Data from PDB ID 4YLN, Y. Zuo and T. A. Steitz, *Mol. Cell* 58:534, 2015.]

The pathway of transcription initiation and the fate of the σ subunit are illustrated in **Figure 26-6**. The pathway consists of two major parts, binding and initiation, each with multiple steps. First, the polymerase, directed by its bound σ factor, binds to the promoter. A **closed complex** (in which the bound DNA remains double-stranded) and an **open complex** (in which the bound DNA is partially unwound near the −10 sequence) form in succession. Second, transcription is initiated within the complex, leading to a conformational change that converts the complex to the elongation form, followed by movement of the transcription complex away from the promoter (promoter clearance). Any of these steps can be affected by the specific makeup of the promoter sequences. The σ subunit dissociates at random as the polymerase enters the elongation phase of transcription. The protein NusA (M_r 54,430) binds to the elongating RNA polymerase, competitively with the σ subunit. Once transcription is complete, NusA dissociates from the enzyme, the RNA polymerase dissociates from the DNA, and a σ factor (σ^{70} or another) can again bind to the enzyme to initiate transcription.

E. coli has other classes of promoters bound by RNA polymerase holoenzymes with different σ subunits, such as the promoters of the heat shock genes. The products of this set of genes are made at higher levels when the cell is exposed to environmental stress, such as a sudden increase in temperature. RNA polymerase binds to the promoters of these genes only when σ^{70} is replaced with the σ^{32} (M_r 32,000) subunit, which is specific for the heat shock promoters (see Fig. 28-3). By using different σ subunits, the cell can coordinate the expression of sets of genes, permitting major changes in cell physiology. Which sets of genes are expressed is determined by the availability of the various σ subunits. This, in turn, is determined by several factors: regulated rates of synthesis and degradation, posttranslational modifications that switch individual σ subunits between active and inactive forms, and a specialized class of anti-σ proteins, each type binding to and sequestering a particular σ subunit to render it unavailable for transcription initiation.

BOX 26-1 METHODS

RNA Polymerase Leaves Its Footprint on a Promoter

Footprinting, a technique derived from principles used in DNA sequencing, identifies the DNA sequences bound by a particular protein. Researchers isolate a DNA fragment thought to contain sequences recognized by a DNA-binding protein, and then radiolabel one end of one strand (Fig. 1). They then use chemical or enzymatic reagents to introduce random breaks in the DNA fragment (averaging about one break per molecule). Separation of the labeled cleavage products (broken fragments of various lengths) by high-resolution electrophoresis produces a ladder of radioactive bands. In a separate tube, the cleavage procedure is repeated on copies of the same DNA fragment in the presence of the DNA-binding protein. The researchers then subject the two sets of cleavage products to electrophoresis and compare them side by side. A gap ("footprint") in the series of radioactive bands derived from the DNA-protein sample, attributable to protection of the DNA by the bound protein, identifies the sequences that the protein binds.

The precise location of the protein-binding site can be determined by directly sequencing (see Fig. 8-35) copies of the same DNA fragment and including the sequencing lanes (not shown here) on the same gel with the footprint. Figure 2 shows footprinting results for the binding of RNA polymerase to a DNA fragment containing a promoter. The polymerase covers 60 to 80 bp; protection by the bound enzyme includes the −10 and −35 regions.

① RNA polymerase core and the σ^{70} subunit bind to the DNA promoter.

② Transcription bubble forms.

③ Transcription is initiated.

④ Promoter clearance is followed by elongation.

⑤ Elongation continues. σ^{70} dissociates, and is replaced by NusA.

⑥ Transcription is terminated. NusA dissociates, and the RNA polymerase is recycled.

FIGURE 26-6 Transcription initiation and elongation by *E. coli* RNA polymerase. Initiation of transcription requires several steps generally divided into two phases: binding and initiation. In the binding phase, the initial interaction of the RNA polymerase with the promoter leads to formation of a closed complex, in which the promoter DNA is stably bound but not unwound. A 12 to 15 bp region of DNA—from within the −10 region to position +2 or +3—is then unwound to form an open complex. Additional intermediates (not shown) have been detected in the pathways leading to the closed and open complexes, along with several changes in protein conformation. The initiation phase encompasses promoter binding, transcription initiation, and promoter clearance (steps ① through ④ here). Once elongation commences, the σ subunit is released and is replaced by the protein NusA. The polymerase leaves the promoter and becomes committed to elongation of the RNA (step ⑤). When transcription is complete, the RNA is released, the NusA protein dissociates, and the RNA polymerase dissociates from the DNA (step ⑥). Another σ subunit binds to the RNA polymerase and the process begins again.

Transcription Is Regulated at Several Levels

Requirements for any gene product vary with cellular conditions or developmental stage, and transcription of each gene is carefully regulated to form gene products only in the proportions needed. P1 Regulation can occur at any step of transcription, including elongation and termination. However, much of the regulation is directed at the polymerase binding and transcription initiation steps outlined in Figure 26-6. Differences in promoter sequences are just one of several levels of control.

The binding of proteins to sequences both near to and distant from the promoter can also affect levels of gene expression. Protein binding can *activate* transcription by facilitating either RNA polymerase binding or steps farther along in the initiation process, or it can *repress* transcription by blocking the activity of the polymerase. In *E. coli*, one protein that activates transcription is the **cAMP receptor protein (CRP)**, which increases the transcription of genes coding for enzymes that metabolize sugars other than glucose when cells are grown in the absence of glucose. **Repressors** are proteins that block the synthesis of RNA at specific genes. In the case of the Lac repressor, transcription of the genes for the enzymes of lactose metabolism is blocked when lactose is unavailable.

As described further in Chapter 27, transcription of mRNAs and their translation are tightly coupled in bacteria. As a protein-coding gene is being transcribed, ribosomes rapidly bind to and begin to translate the mRNA before its synthesis is complete. Another protein, NusG, binds directly to both the ribosome and RNA polymerase, linking the two complexes. The rate of translation directly affects the rate of transcription. In contrast, eukaryotes carry out transcription in the nucleus and translation in the cytoplasm, making it impossible for these two steps to be physically coupled.

Specific Sequences Signal Termination of RNA Synthesis

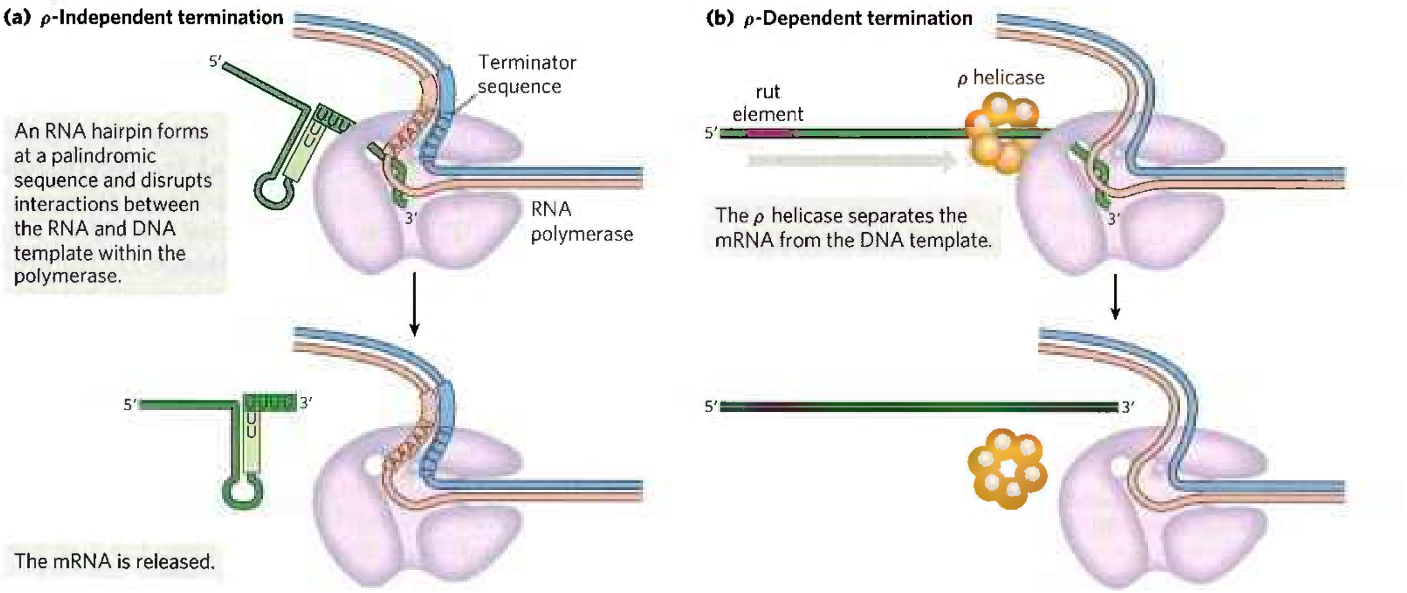
RNA synthesis is processive; that is, the RNA polymerase introduces a large number of nucleotides into a growing RNA molecule before dissociating (p. 917). This is necessary because, if the polymerase released an RNA transcript prematurely, it could not resume synthesis of the same RNA and would have to start again from the beginning of the gene. However, an encounter with certain DNA sequences results in a pause in RNA synthesis, and at some of these sequences transcription is terminated. Our focus here is again on the well-studied systems in bacteria. *E. coli* has at least two classes of termination signals: one class relies on a protein factor called ρ (rho), and the other is ρ-independent.

Most ρ-independent terminators have two distinguishing features. The first is a region that produces an RNA transcript with self-complementary sequences, permitting the formation of a hairpin structure (see Fig. 8-19a) centered 15 to 20 nucleotides before the projected end of the RNA strand. The second feature is a highly conserved string of three A residues in the template strand that are transcribed into U residues near the 3′ end of the hairpin. When a polymerase arrives at a termination site with this structure, it pauses (**Fig. 26-7a**). Formation of the hairpin structure in the RNA disrupts several A=U base pairs in the RNA-DNA hybrid segment and may disrupt important interactions between RNA and the RNA polymerase, facilitating dissociation of the transcript.

The ρ-dependent terminators lack the sequence of repeated A residues in the template strand but usually include a CA-rich sequence called a *rut* (*r*ho *ut*ilization) element. The ρ protein associates with the RNA at specific binding sites and migrates in the 5′→3′ direction until it reaches the transcription complex that is paused at a termination site (Fig. 26-7b). Here it promotes release of the RNA transcript. The ρ protein has an ATP-dependent RNA-DNA helicase activity that permits translocation of the protein along the RNA, and ATP is hydrolyzed by the ρ protein during the termination process. The detailed mechanism by which the protein promotes the release of the RNA transcript is not known.

Eukaryotic Cells Have Three Kinds of Nuclear RNA Polymerases

The transcriptional machinery in the nucleus of a eukaryotic cell is much more complex than that in bacteria. Eukaryotes have three nuclear RNA polymerases, designated I, II, and III, which are distinct complexes but have certain subunits in common. Each polymerase has a specific function (**Table 26-1**) and is recruited to



(a) ρ-Independent termination

An RNA hairpin forms at a palindromic sequence and disrupts interactions between the RNA and DNA template within the polymerase.

The mRNA is released.

(b) ρ-Dependent termination

The ρ helicase separates the mRNA from the DNA template.

FIGURE 26-7 Termination of transcription in *E. coli*. (a) ρ-Independent termination. RNA polymerase pauses at a variety of DNA sequences, some of which are terminators. One of two outcomes is then possible: either the polymerase bypasses the site and continues on its way, or the complex undergoes a conformational change (isomerization). During isomerization, intramolecular pairing of complementary sequences in the newly formed RNA transcript may form a hairpin that disrupts the RNA-DNA hybrid, the interactions between RNA and polymerase, or both. An A=U hybrid region at the 3′ end of the new transcript is relatively unstable, and the RNA dissociates from the complex completely, leading to termination. At nonterminating pause sites, the complex may escape after the isomerization step to continue RNA synthesis. (b) ρ-Dependent termination. RNAs that include a rut element recruit the ρ helicase. The ρ helicase migrates along the mRNA in the 5′→3′ direction and separates it from the polymerase.

TABLE 26-1 Eukaryotic Nuclear RNA Polymerases

RNA polymerase	Types of RNA synthesized

a specific promoter sequence. In addition, eukaryotic mitochondria and chloroplasts have their own RNA polymerases for transcription of genes encoded in their own DNA (see Fig. 19-40). The RNA polymerases in these organelles are similar to bacterial RNA polymerases and less elaborate than the nuclear transcription machinery discussed below.

RNA polymerase I (Pol I) is responsible for the synthesis of only one type of RNA, a transcript called pre-ribosomal RNA (or pre-rRNA), which contains the precursor for the 18S, 5.8S, and 28S rRNAs. The principal function of RNA polymerase II (Pol II) is the synthesis of mRNAs and many ncRNAs. This enzyme can recognize thousands of promoters that vary greatly in sequence. Some Pol II promoters have a few sequence features in common, including a TATA box (eukaryotic consensus sequence TATA(A/T)A(A/T)(A/G)) near base pair −30 and an Inr sequence (initiator) near the RNA start site at +1 (**Fig. 26-8**). However, such promoters are in the minority, and elaborate interactions with regulatory proteins guide Pol II function at many promoters that lack these features.

RNA polymerase III (Pol III) makes tRNAs, the 5S rRNA, and other small, specialized ncRNAs, including the U6 RNA component of the spliceosome, which we will discuss in Section 26.2. The promoters recognized by Pol III are well characterized. Some of the sequences required for the regulated initiation of transcription by Pol III are located within the gene itself, whereas others are in more conventional locations upstream of the RNA start site (Chapter 28).

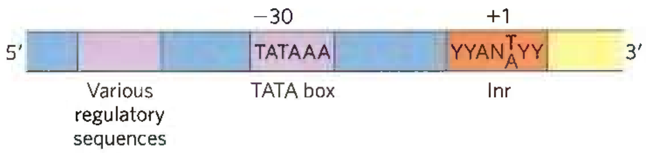

FIGURE 26-8 Some common features of TATA box promoters recognized by eukaryotic RNA polymerase II. The TATA box is the major assembly point for the proteins of the preinitiation complexes of Pol II. The DNA is unwound at the initiator sequence (Inr), and the transcription start site is usually within or very near this sequence. In the Inr consensus sequence shown here, N represents any nucleotide and Y represents a pyrimidine nucleotide. Additional sequences around the TATA box and downstream (to the right as shown here) of Inr may be recognized by one or more transcription factors. The sequence elements of Pol II promoters summarized here are much more variable and complex in comparison to *E. coli* promoters (see Fig. 26-5).

RNA Polymerase II Requires Many Other Protein Factors for Its Activity

RNA polymerase II is central to eukaryotic gene expression and has been studied extensively. P1 Although this polymerase is strikingly more complex than its bacterial counterpart, the complexity masks a remarkable conservation of structure, function, and mechanism. Pol II isolated from either yeast or human cells is a 12-subunit enzyme with an aggregate molecular weight of more than 510,000. The largest subunit (RBP1) exhibits a high degree of homology to the β' subunit of bacterial RNA polymerase. Another subunit (RBP2) is structurally similar to the bacterial β subunit, and two others (RBP3 and RBP11) show some structural homology to the two bacterial α subunits. Pol II must function with genomes that are more complex and with DNA molecules more elaborately packaged than in bacteria. The need for protein-protein contacts with the numerous other protein factors required to navigate this labyrinth accounts in large measure for the added complexity of the eukaryotic polymerase.

The largest subunit of Pol II (RBP1) also has an unusual feature, a long carboxyl-terminal tail consisting of many repeats of a consensus heptad amino acid sequence, —YSPTSPS—. There are 26 repeats in the yeast enzyme (19 exactly matching the consensus) and 52 (21 exact) in the mouse and human enzymes. This **carboxyl-terminal domain (CTD)** is separated from the main body of the enzyme by an intrinsically disordered linker sequence. The CTD has many important roles in Pol II function, as outlined below.

RNA polymerase II requires an array of other proteins, called **transcription factors**, to form the active transcription complex. The **general transcription factors** required at every Pol II promoter (factors usually designated TFII with an additional identifier) are highly conserved in all eukaryotes (**Table 26-2**). The process of transcription by Pol II can be described in terms of several phases—assembly, initiation, elongation, termination—each associated with characteristic proteins (**Fig. 26-9**). The step-by-step pathway described below leads to active transcription in vitro. In the cell, many of the proteins may be present in larger, preassembled complexes, simplifying the pathways for assembly on promoters. As you read about this process, consult Figure 26-9 and Table 26-2 to help keep track of the many participants.

Assembly of RNA Polymerase and Transcription Factors at a Promoter The formation of a closed complex begins when the TATA-binding protein (TBP) binds to the TATA box (Fig. 26-9a, step ①). At promoters lacking a TATA box, TBP arrives as part of a multisubunit complex called

TABLE 26-2 Proteins Required for Initiation of Transcription at the RNA Polymerase II (Pol II) Promoters of Eukaryotes

Transcription protein	Number of different subunits	Subunit(s) M_r[a]	Function(s)
Initiation			
Pol II	12	7,000–220,000	Catalyzes RNA synthesis
TBP (TATA-binding protein)	1	38,000	Specifically recognizes the TATA box
TFIIA	2	13,000, 42,000	Stabilizes binding of TFIIB and TBP to the promoter
TFIIB	1	35,000	Binds to TBP; recruits Pol II–TFIIF complex
TFIID[b]	13–14	14,000–213,000	Required for initiation at promoters lacking a TATA box
TFIIE	2	33,000, 50,000	Recruits TFIIH; has ATPase and helicase activities
TFIIF	2–3	29,000–58,000	Binds tightly to Pol II; binds to TFIIB and prevents binding of Pol II to nonspecific DNA sequences
TFIIH	10	35,000–89,000	Unwinds DNA at promoter (helicase activity); phosphorylates Pol II CTD; recruits nucleotide-excision repair proteins
Elongation[c]			
ELL[d]	1	80,000	
pTEFb	2	43,000, 124,000	Phosphorylates Pol II CTD
SII (TFIIS)	1	38,000	
Elongin (SIII)	3	15,000, 18,000, 110,000	

[a] M_r reflects the subunits present in the complexes of human cells.

[b] The presence of multiple copies of some TFIID subunits brings the total subunit composition of the complex to 21–22.

[c] The function of all elongation factors is to suppress the pausing or arrest of transcription by the Pol II–TFIIF complex.

[d] Name derived from eleven-nineteen *l*ysine-rich *l*eukemia. The gene for ELL is the site of chromosomal recombination events frequently associated with acute myeloid leukemia.

TFIID. TBP is bound, in turn, by the transcription factor TFIIB. TFIIA then binds and, along with TFIIB, helps to stabilize the TBP-DNA complex. The TFIIB-TBP complex is next bound by another complex consisting of TFIIF and Pol II. TFIIF helps target Pol II to its promoters, both by interacting with TFIIB and by reducing the binding of the polymerase to nonspecific sites on the DNA. Finally, TFIIE and TFIIH bind to create the closed, **preinitiation complex (PIC)**.

A key function of TFIID in the PIC is to position TBP on the promoter, which in turn dictates the location of Pol II loading and transcription initiation. Because most human promoters (~80%) lack a TATA box, how TFIID correctly positions TBP and Pol II relative to the transcription start site was poorly understood until their structures were determined by cryo-EM (Fig. 26-9b). These structures showed that TFIID binds the promoter DNA in an elongated complex that is anchored by TBP–DNA interactions on one end and extends linearly over 70 base pairs. The **Inr sequence** is positioned roughly in the middle, straddled on both ends by TFIID subunits. TFIID thus acts as a scaffold to direct binding of Pol II and other PIC components and uses its structure and interactions with TBP to help define the transcription start site.

TFIIH has multiple subunits and includes a DNA helicase activity that promotes the unwinding of DNA near the RNA start site (a process requiring the hydrolysis of ATP), thereby creating an open initiation complex (Fig. 26-9a, step ❷). Counting all the subunits of the various factors (including TFIIA and the subunits of TFIID), this active initiation complex can have more than 50 polypeptides.

RNA Strand Initiation and Promoter Clearance TFIIH has an additional function during the initiation phase. A kinase activity in one of its subunits phosphorylates Pol II at many places in the CTD (Fig. 26-9a, step ❸). Several other protein kinases, including CDK9 (cyclin-dependent kinase 9), which is part of the complex pTEFb (positive transcription elongation factor b), also phosphorylate the CTD, primarily on Ser residues of the CTD repeat sequence. CTD phosphorylation causes a conformational change in the overall complex, initiating transcription. During the subsequent elongation phase of transcription, the phosphorylation state of the CTD changes, affecting which RNA processing components are bound to the transcription complexes (**Fig. 26-10**).

During synthesis of the initial 60 to 70 nucleotides of RNA, first TFIIE, then TFIIH is released, and Pol II enters the elongation phase of transcription (Fig. 26-9a, step ❹).

Elongation, Termination, and Release TFIIF remains associated with Pol II throughout elongation. During this stage, polymerase activity is greatly enhanced by protein elongation factors (Table 26-2). The elongation factors,

FIGURE 26-9 Transcription at RNA polymerase II promoters. (a) TBP (often with TFIIA and sometimes with TFIID) and TFIIB bind sequentially to a promoter. TFIIF plus Pol II are then recruited to that complex. The further addition of TFIIE and TFIIH results in a closed complex. Within the complex, the DNA is unwound at the Inr region by the helicase activity of TFIIH and perhaps of TFIIE, creating an open complex that completes assembly. The carboxyl-terminal domain of the largest Pol II subunit is phosphorylated by TFIIH, and the polymerase then escapes the promoter and initiates transcription. Elongation is accompanied by the release of many transcription factors and is also enhanced by elongation factors (see Table 26-2). After termination, Pol II is released, dephosphorylated, and recycled. (b) Structure of the human TFIIA/TFIID/TBP complex bound to promoter DNA, determined by cryo-EM. The DNA is stretched linearly over 70 base pairs, with the Inr sequence positioned roughly in the middle of TFIID, anchored by TBP/TATA-box interactions on the end. [(a) Information from E. FIGURE 26-10 Phosphorylation of the carboxyl-terminal domain (CTD) of RNA polymerase II. The phosphorylation pattern of the CTD changes during different phases of transcription due to the action of kinases and phosphorylases associated with the transcription machinery. Multiple repeats of the CTD tail are phosphorylated with the patterns shown here during each stage; however, these are not shown for clarity. Understanding the patterns and heterogeneity of CTD tail phosphorylation at different stages of transcription and on different genes is an active area of transcription research.

some bound to the phosphorylated CTD, suppress pausing during transcription and also coordinate interactions between the supramolecular complexes involved in the posttranscriptional processing of mRNAs. Once the RNA transcript is completed, transcription is terminated (Fig. 26-9a, step ⑤). The Pol II CTD is dephosphorylated and the transcription machinery recycled, ready to initiate another transcript.

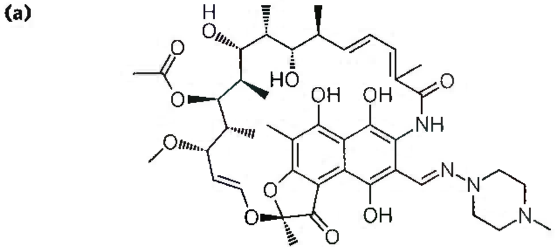
Regulation of transcription at Pol II promoters is an elaborate process. It involves the interaction of a wide variety of other proteins with the preinitiation complex. Some of these regulatory proteins interact with transcription factors, others with Pol II itself. The regulation of eukaryotic transcription is described in more detail in Chapter 28.

RNA Polymerases Are Drug Targets

Both bacterial and eukaryotic RNA polymerases are the targets of a large number of chemical inhibitors. Some of these molecules inhibit transcription of both types of RNA polymerases; others selectively inhibit only certain types of polymerase.

The elongation of RNA strands by RNA polymerase in both bacteria and eukaryotes is inhibited by the antibiotic **actinomycin D**. The planar portion of this molecule inserts (intercalates) into the double-helical DNA between successive G≡C base pairs, deforming the DNA duplex. This prevents movement of the polymerase along the DNA during transcription. Because actinomycin D inhibits RNA elongation in intact cells as well as in cell extracts, it can be used to identify cell processes that depend on RNA synthesis.

Rifampin (Fig. 26-11a) inhibits bacterial RNA synthesis by preventing the promoter clearance step of transcription. Rifampin is an important antibiotic for the treatment of tuberculosis (TB), which is caused by the bacterium *Mycobacterium tuberculosis* and kills approximately 1.8 million people each year. The antibiotic



Rifampin

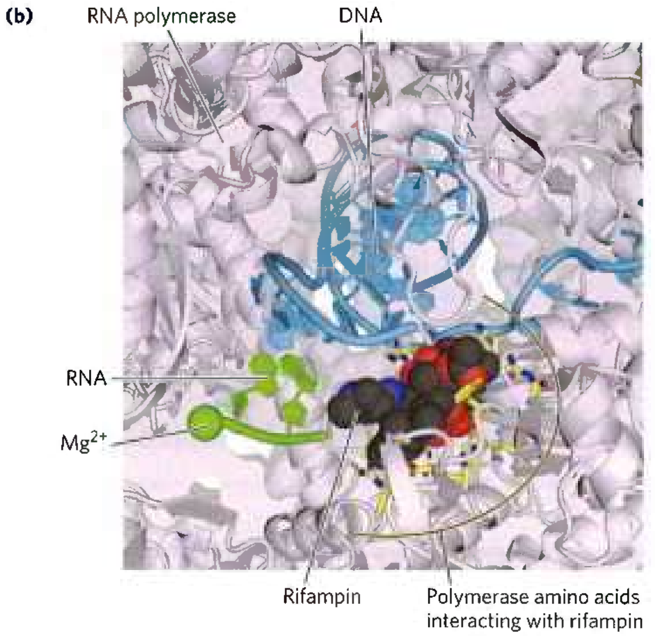


FIGURE 26-11 Inhibition of RNA polymerase by rifampin. (a) Chemical structure of rifampin. (b) X-ray crystallographic structure of rifampin bound to the active site of *M. tuberculosis* RNA polymerase. In this slab view, much of the surrounding polymerase has been removed so that active site details, including one of the essential Mg^{2+} ions, can be highlighted. Rifampin (shown in spacefill) binds within the active site and blocks extension of the RNA transcript. Many RNA polymerase amino acids make direct contact with rifampin, and mutation of these amino acids can result in rifampicin-resistant RNA polymerase and TB infection. [(b) Data from PDB ID 5UH6 and information from W. Lin et al., *Mol. Cell* 66:169, 2017.]

binds near the active site of RNA polymerase and prevents extension of the RNA product beyond 2 to 3 nucleotides. Unfortunately, *M. tuberculosis* can develop resistance to rifampin; more than 600,000 cases of rifampin-resistant TB are reported each year. In many cases, resistance is due to mutation in the rifampin binding site (Fig. 26-11b), particularly at Asp^{516}, His^{526}, and Ser^{531} of the β subunit. New drugs that inhibit *M. tuberculosis* RNA polymerase are desperately needed for treatment of drug-resistant TB.

The death cap mushroom *Amanita phalloides* has a very effective defense mechanism against predators. It produces **α-amanitin**, which disrupts transcription in animal cells by blocking Pol II and, at higher concentrations, Pol III. Neither Pol I nor bacterial RNA polymerase is sensitive to α-amanitin—nor is the RNA polymerase II of *A. phalloides* itself. Because α-amanitin is selective for inhibiting the function of only certain RNA polymerases, it has proven useful for identifying the functions of different polymerases in the cell. Mitochondrial and bacterial RNA polymerases share significant similarities to one another, including α-amanitin resistance. By exposing eukaryotic cells to α-amanitin, it is possible to detect newly synthesized mRNAs that arise only from mitochondrial and not nuclear transcription. Researchers using α-amanitin need to exercise abundant caution because it is highly toxic to humans. An amount of α-amanitin the size of a grain of rice contains a lethal dose. ■

SUMMARY 26.1 *DNA-Dependent Synthesis of RNA*

- Transcription is catalyzed by DNA-dependent RNA polymerases, which use ribonucleoside 5′-triphosphates to synthesize RNA in the 5′→3′ direction, complementary to the template strand of duplex DNA. Transcription occurs in several phases: binding of RNA polymerase to a DNA site called a promoter, initiation of transcript synthesis, elongation, and termination.
- RNA polymerases bind regions of DNA called promoters to initiate transcription of nearby genes. Promoter sequences help to establish the level of gene expression and in *E. coli* are recognized by variable RNA polymerase subunits called σ factors. Transcription initiation involves formation of the closed and open complexes. DNA is unwound in the open complex to allow it to serve as the transcription template.
- As the first committed steps in transcription, binding of RNA polymerase to the promoter and initiation of transcription are closely regulated.
- Bacterial transcription stops at sequences called terminators. *E. coli* commonly uses two types of termination signals: ρ-dependent and ρ-independent.
- Eukaryotic cells have three types of nuclear RNA polymerases. The vast majority of cellular mRNAs and ncRNAs are synthesized by Pol II.
- Binding of Pol II to its promoters requires an array of proteins called transcription factors. Ultimately, a large molecular complex called the preinitiation complex, PIC, forms at the promoter. Elongation factors participate in the elongation phase of transcription. The phosphorylation state of the long carboxyl-terminal domain of the largest Pol II subunit changes in the initiation and elongation phases and determines what components are part of the initiation and elongation complexes.
- RNA polymerases can be inhibited by a number of drugs, some of which are specific to either bacterial or eukaryotic polymerases. Drugs that inhibit bacterial RNA polymerase are commonly used to treat infections such as tuberculosis.

26.2 RNA Processing

P2 Many of the RNA molecules in bacteria and virtually all RNA molecules in eukaryotes are processed to some degree after synthesis. Processing can include addition or deletion of nucleotide sequences as well as chemical modification of RNA nucleotides. All of these events can be used to control the posttranscriptional fate of the RNA in the cell. As a result, many mature RNAs are not exact copies of the DNA genes from which they were transcribed. Some of the most interesting molecular events in RNA metabolism occur during posttranscriptional processing. Intriguingly, several of the enzymes that catalyze these reactions have active sites composed of RNA rather than protein. The discovery of these catalytic RNAs, or **ribozymes**, has brought a revolution in thinking about RNA function and about the origin of life, as we will discuss in Section 26.4.

A newly synthesized RNA molecule is called a **primary** or **precursor transcript**. Perhaps the most extensive processing of primary transcripts occurs in eukaryotic precursor mRNAs (pre-mRNAs) and in the tRNAs of both bacteria and eukaryotes. However, many ncRNAs are also processed.

The precursor transcript for a eukaryotic mRNA typically contains sequences encompassing one gene, although the sequences encoding the polypeptide may not be contiguous. Noncoding tracts that break up the coding region of the transcript are called **introns**, and the coding segments are called **exons** (see the discussion of introns and exons in DNA in Chapter 24). **P2** In a process called **RNA splicing**, the introns are removed from the pre-mRNA, and the exons are spliced together to form a continuous sequence that specifies a functional polypeptide. Virtually all human genes contain introns, the average being eight introns per gene. Eukaryotic mRNAs are also modified at each end. A modified nucleotide structure called a 5′ cap is added at the 5′ end. The 3′ end is cleaved, and 80 to 250 A residues are added to create a poly(A) "tail." The sometimes elaborate protein complexes that carry out 5′ capping, splicing, and 3′ polyadenylation mRNA-processing reactions do not operate independently. They are organized in association with each other and with the phosphorylated CTD of Pol II; each complex affects the function of the others, as outlined in **Figure 26-12**.

Proteins involved in mRNA transport to the cytoplasm are also associated with the mRNA in the nucleus, and the processing of the transcript is coupled to its transport. In effect, a eukaryotic mRNA, as it is synthesized, is ensconced in an elaborate and dynamic supramolecular **messenger ribonucleoprotein (mRNP) complex** comprising dozens of proteins. The composition of the mRNP changes as the transcript is processed, transported to the cytoplasm, and delivered to the ribosome for translation. Associated proteins can dramatically modulate the cellular destination, function, and fate of an mRNA.

In addition to splicing and 5′ and 3′ end modification, individual purine and pyrimidine nucleotides within primary transcripts can undergo chemical modification. Many eukaryotic mRNAs contain modified nucleotides that affect their interactions with RNA-binding proteins and regulate gene expression; however, RNA modification has been best characterized in primary tRNA transcript processing. Many bases and sugars in tRNAs are modified in both bacteria and eukaryotes, including with unusual bases not found in other nucleic acids (see

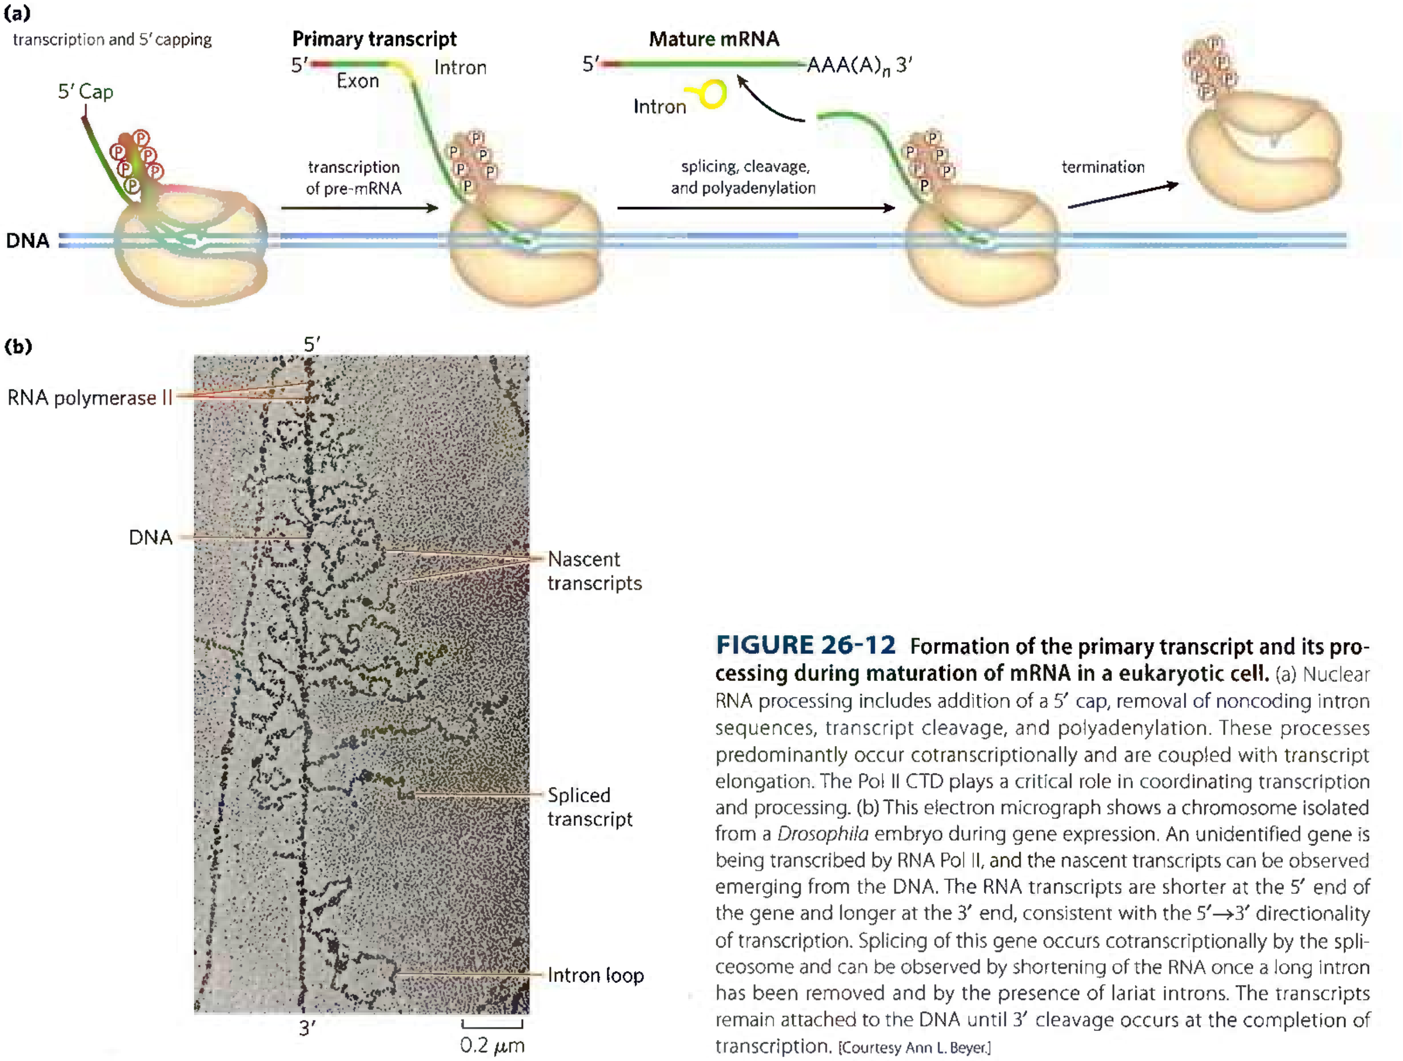

FIGURE 26-12 Formation of the primary transcript and its processing during maturation of mRNA in a eukaryotic cell. (a) Nuclear RNA processing includes addition of a 5′ cap, removal of noncoding intron sequences, transcript cleavage, and polyadenylation. These processes predominantly occur cotranscriptionally and are coupled with transcript elongation. The Pol II CTD plays a critical role in coordinating transcription and processing. (b) This electron micrograph shows a chromosome isolated from a *Drosophila* embryo during gene expression. An unidentified gene is being transcribed by RNA Pol II, and the nascent transcripts can be observed emerging from the DNA. The RNA transcripts are shorter at the 5′ end of the gene and longer at the 3′ end, consistent with the 5′→3′ directionality of transcription. Splicing of this gene occurs cotranscriptionally by the spliceosome and can be observed by shortening of the RNA once a long intron has been removed and by the presence of lariat introns. The transcripts remain attached to the DNA until 3′ cleavage occurs at the completion of transcription. [Courtesy Ann L. Beyer.]

Fig. 26-22). Many ncRNAs also undergo elaborate processing, often involving the removal of segments from one or both ends.

The ultimate fate of any RNA is its complete and regulated degradation. The rate of turnover of RNAs plays a critical role in determining their steady-state levels and the rate at which cells can shut down expression of a gene when its product is no longer needed. During the development of multicellular organisms, for example, certain proteins must be expressed at one stage only, and the mRNA encoding such a protein must be made and destroyed at the appropriate times.

Eukaryotic mRNAs Are Capped at the 5′ End

P2 Most eukaryotic mRNAs have a **5′ cap**, a residue of 7-methylguanosine linked to the 5′-terminal residue of the mRNA through an unusual 5′,5′-triphosphate linkage (**Fig. 26-13**). The 5′ cap helps protect mRNA from ribonucleases. It also binds to specific cap-binding complexes of proteins and participates in binding of the mRNA to the ribosome to initiate translation (Chapter 27).

The 5′ cap is formed by condensation of a molecule of GTP with the triphosphate at the 5′ end of the transcript. The guanine is subsequently methylated at N-7, and additional methyl groups are often added at the 2′ hydroxyls of the first and second nucleotides adjacent to the cap (Fig. 26-13a). The methyl groups are derived from *S*-adenosylmethionine. All these reactions (Fig. 26-12b) occur very early in transcription, after the first 20 to 30 nucleotides of the transcript have been added. All four of the enzymes in the cap-synthesizing complex, and through them the 5′ end of the transcript itself, are associated with the RNA polymerase II CTD (Fig. 26-13c) until the cap is synthesized. The capped 5′ end is then released from the cap-synthesizing complex and bound by the nuclear cap-binding complex, which facilitates both splicing and nuclear export of the RNA.

The 5′ cap does not provide permanent protection of the transcript. Eukaryotes also contain cellular decapping enzymes, which are important for RNA regulation. Cap removal allows RNAs to be degraded by exonucleases that hydrolyze the RNA in the 5′→3′ direction. Some viruses have also evolved elaborate mechanisms for removing the 5′ cap from host mRNAs. The influenza virus needs no specialized enzymes for the synthesis of 5′ caps on its viral RNAs; instead, it borrows these

Methyl groups (shaded) are often found at the 2′ position of the first and second nucleotides in vertebrate cells. (b) Generation of the 5′ cap requires four separate steps (adoHcy is *S*-adenosylhomocysteine). (c) Synthesis of the cap is carried out by enzymes tethered to the CTD of Pol II. Shown here is the structure of the guanylyltransferase subunit of the mouse capping enzyme in complex with a peptide mimicking the Pol II CTD repeat sequence (YSPTSPS). The guanylyltransferase specifically recognizes the first residue (Tyr) and the phosphorylated form of the fifth residue (Ser). [(c) Data from PDB ID 3RTX, A. Ghosh et al., *Mol. Cell* 43:299, 2011.]

structures from host-cell transcripts in a process termed "cap-snatching." A capped host transcript is bound by the viral RNA polymerase and cleaved by an endonuclease. The influenza RNA polymerase can then use the resulting capped oligonucleotide to prime viral RNA synthesis.

Both Introns and Exons Are Transcribed from DNA into RNA

In bacteria, the mRNA used for translation is generally a direct copy of the DNA gene sequence, continuing along the DNA template without interruption until the information needed to specify the polypeptide is complete. However, the notion that *all* genes are continuous was disproved in 1977 when Phillip Sharp and Richard Roberts independently discovered that many genes for polypeptides in eukaryotes are interrupted by noncoding sequences (introns).

P2 The vast majority of genes in vertebrates contain introns; among the few exceptions are those that encode histones. The occurrence of introns in other eukaryotes varies. Many genes of the yeast *Saccharomyces cerevisiae* lack introns, but introns are more common in some other yeast species. Introns are also found in a few bacterial and archaeal genes. Introns in DNA are transcribed along with the rest of the gene by RNA polymerases. The introns in the primary RNA transcript are then spliced, and the exons are joined to form a mature, functional RNA. In eukaryotic mRNAs, most exons are less than 1,000 nucleotides long, with many in the 100 to 200 nucleotide size range, encoding stretches of 30 to 60 amino acids within a longer polypeptide. Introns vary in size from 50 to more than 700,000 nucleotides, with a median length of about 1,800. Genes of higher eukaryotes, including humans, typically have much more DNA devoted to introns than to exons. For example, the human dystrophin gene encodes a pre-mRNA more than 2 million nucleotides long. However, the final mRNA is 14,000 nucleotides long, indicating that more than 99% of the transcribed RNA is found within introns and removed by splicing. Deficiencies in dystrophin expression can lead to muscular dystrophies. The ~20,000 genes of the human genome include more than 200,000 introns.

RNA Catalyzes the Splicing of Introns

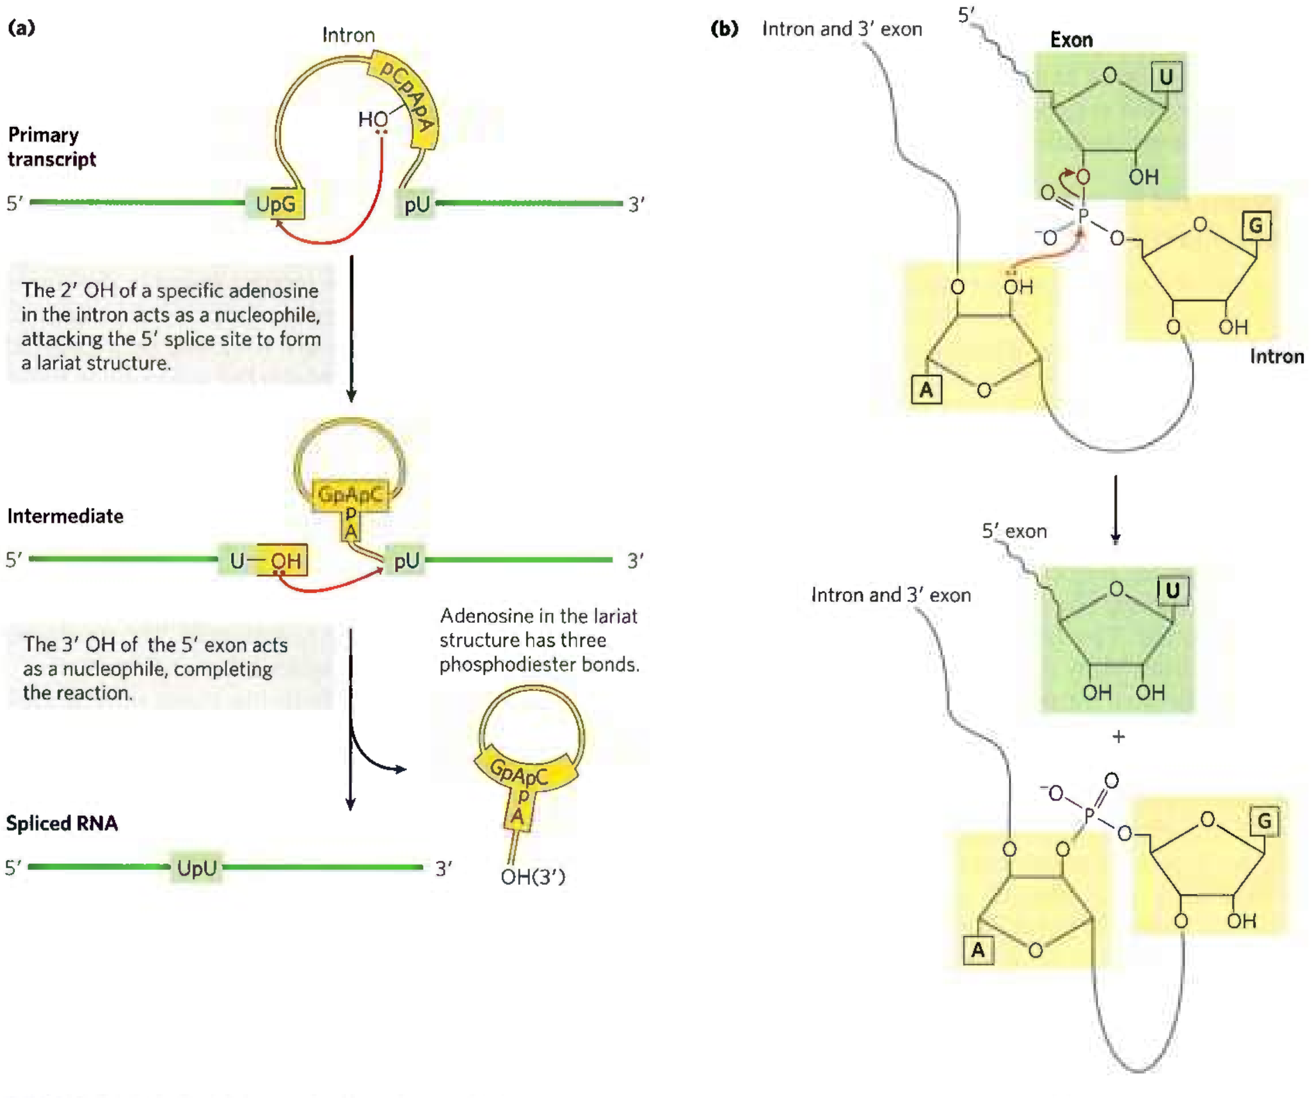
There are four classes of introns (**Table 26-3**). The first two, the group I and group II introns, differ in the details of their splicing mechanisms but share one surprising characteristic: they are *self-splicing*—no proteins are needed to carry out catalysis. The introns found in the nuclear-encoded genes of eukaryotes comprise the third class. These pre-mRNA introns are removed by a large RNP called the spliceosome. Although the spliceosome requires dozens of proteins for its function, its active site includes RNA. The final class of introns requires protein enzymes for their removal. These introns are found in some tRNAs as well as certain mRNAs, such as that encoding the Xbox binding protein 1, Xbp1. Protein-mediated splicing of the XBP1 transcript regulates the cellular response to unfolded proteins that occurs under conditions of endoplasmic reticulum stress in human cells. The mechanisms of tRNA and XBP1 mRNA splicing are similar.

Group I introns are found in some nuclear, mitochondrial, and chloroplast genes that code for rRNAs, mRNAs, and tRNAs. Group II introns are generally found in the primary transcripts of mitochondrial or chloroplast mRNAs in fungi, algae, and plants. Group I and group II introns are also among the rare examples of introns in bacteria. The splicing mechanisms in both groups involve two transesterification reaction steps (**Fig. 26-14**), in which a ribose 2′- or 3′-hydroxyl group makes a nucleophilic attack on a phosphorus, and a new phosphodiester bond is formed at the expense of the old, maintaining the balance of energy. These reactions are very similar to the DNA breaking and rejoining reactions promoted by topoisomerases (see Fig. 24-18) and site-specific recombinases (see Fig. 25-37).

The group I splicing reaction requires a guanine nucleoside or nucleotide cofactor, but the cofactor is not used as a source of energy; instead, the 3′-hydroxyl group of guanosine is used as a nucleophile in the first step of the

TABLE 26-3 Mechanisms of RNA Splicing

Mechanism	Components	Features	Cellular locations
Group I Intron	Catalytic RNA	Self-splicing using a guanine-derived cofactor	Found in nuclear, mitochondrial, and chloroplast genes that encode mRNAs, rRNAs, or tRNAs. Can be found in bacteria.
Group II Intron	Catalytic RNA; maturase and reverse transcriptase proteins	Self-splicing using a nucleophile within the intron to form a lariat	Primarily found in mitochondrial and chloroplast genes of fungi, algae, and plants. Can be found in bacteria.
Spliceosome	Catalytic snRNAs; dozens of protein splicing factors	Requires a large RNP for processing using a nucleophile within the intron to form a lariat	Found in nuclear genes of eukaryotes. Capable of alternative splicing to create multiple products from a given transcript.
Protein-catalyzed	Protein enzymes	Uses a splicing endonuclease and ligase	Found in tRNAs and a few mRNAs.



The 2′ OH of a specific adenosine in the intron acts as a nucleophile, attacking the 5′ splice site to form a lariat structure.

The 3′ OH of the 5′ exon acts as a nucleophile, completing the reaction.

Adenosine in the lariat structure has three phosphodiester bonds.

FIGURE 26-14 Splicing mechanism of group II introns. (a) In the first step, the 2′ OH of an internal A residue (called the branch point) attacks the phosphodiester bond at the 5′ splice site, resulting in 5′ splice site cleavage and lariat formation. In the second step, the free 3′ OH of the 5′ exon attacks the phosphodiester bond at the 3′ splice site, resulting in exon ligation and intron-lariat release. The spliceosome uses the same chemistry for intron removal, although different RNA sequences mark the intron boundaries and location of the branch point. (b) In the transesterification reaction that occurs during lariat formation, one phosphodiester bond is broken as a second one is created. This forms a lariatlike structure in which one branch is a 2′,5′-phosphodiester bond (the linkage between the intron branchpoint A and intron G nucleotides).

splicing pathway. In group II splicing reactions, the nucleophile is the 2′-hydroxyl group of an A residue *within* the intron (Fig. 26-14a). A branched lariat structure is formed as an intermediate (Fig. 26-14b). In both group I introns and group II introns, the 3′ hydroxyl of the exon that is displaced in the first step then acts as a nucleophile in a similar reaction at the 3′ end of the intron. The result is precise excision of the intron and ligation of the exons.

Self-splicing of introns was first revealed in 1982 in studies of the splicing mechanism of the group I rRNA intron from the ciliated protozoan *Tetrahymena thermophila*, conducted by Thomas Cech and colleagues. These workers transcribed isolated *Tetrahymena* DNA (including the intron) in vitro, using purified bacterial RNA polymerase. The resulting RNA spliced itself accurately without any protein enzymes from *Tetrahymena*. The discovery that RNAs could have catalytic functions was a milestone in our understanding of biological systems and a major step forward in the understanding of how life probably evolved. Catalytic RNAs like group I and group II introns share many features with protein-based enzymes, including folding into well-defined secondary and tertiary structures (**Fig. 26-15**). Catalytic RNAs and their significance in evolution are described in greater detail in Section 26.4.

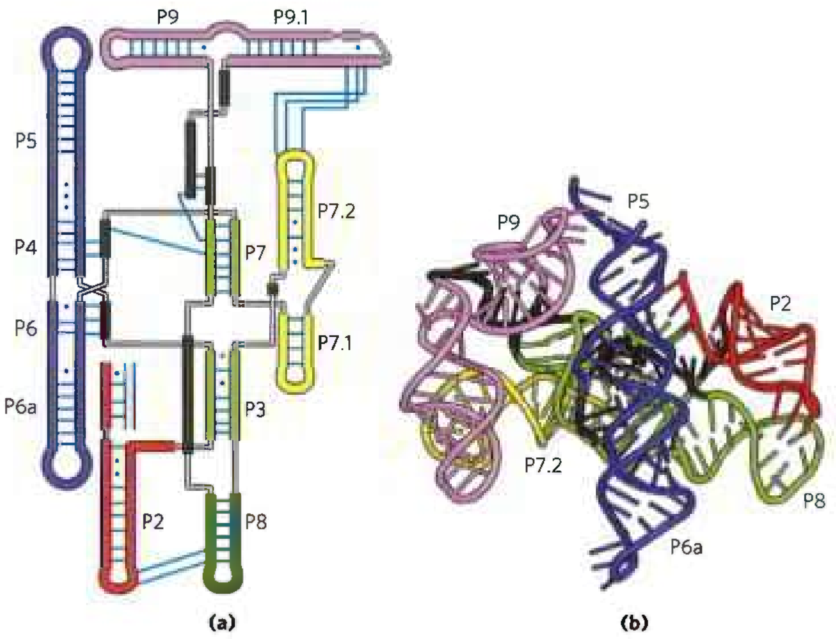

FIGURE 26-15 Structure of a group I intron. (a) The secondary structure of the group I intron ribozyme from phage Twort, a mycobacterium phage named for Frederick Twort, the physician who discovered phage in 1915. Like most catalytic RNAs, this intron adopts well-defined secondary structure. It is composed of multiple RNA duplexes (P2–P9, each differently colored) capped by hairpin structures. (b) The tertiary structure of the intron bound to a spliced RNA product, obtained by x-ray crystallography, shows that the RNA duplexes pack closely with one another to yield a compact ribozyme. The RNA duplexes are colored and named as in (a). [Data from PDB ID 1Y0Q, B. Golden et al., *Nat. Struct. Biol.* 12:82, 2005.]

In Eukaryotes the Spliceosome Carries out Nuclear pre-mRNA Splicing

In eukaryotes, most introns undergo splicing by the same lariat-forming mechanism as the group II introns. P2 However, the intron splicing takes place within a **spliceosome**, a large complex made up of multiple specialized RNP complexes called *s*mall *n*uclear *r*ibo*n*ucleo*p*roteins (snRNPs, pronounced *snurps*) and dozens of non-snRNP proteins. Each snRNP contains one of a class of eukaryotic RNAs, 100 to 200 nucleotides long, known as **small nuclear RNAs (snRNAs)**. Five snRNAs (U1, U2, U4, U5, U6) involved in splicing reactions are generally found in abundance in eukaryotic nuclei. The U3 snRNP is also found in the nucleus but is involved in ribosome assembly and is not part of the spliceosome.

The role of snRNPs in the splicing reaction was discovered by Joan Steitz in a remarkable example of "bedside-to-bench" science. Using antibodies isolated from patients with autoimmune diseases, members of the Steitz laboratory were able to purify the spliceosome's snRNP components and identify the associated snRNAs. Based on complementarity between the 5′ end of the U1 snRNA and the 5′ splice site of nuclear pre-mRNA introns (**Fig. 26-16**), Steitz proposed that snRNPs participate in the splicing reaction. Subsequently, it was discovered that patients suffering from the autoimmune disease lupus can generate antibodies against protein components of their own spliceosomes.

Joan Steitz [Photo by Robert A. Lisak, courtesy Yale School of Medicine.]

In yeast, the various snRNPs include about 80 different proteins, most of which have close homologs in all other eukaryotes. In humans, these conserved protein components are augmented by more than 200 additional proteins, which mostly participate in regulating the splicing reaction. Spliceosomes are thus among the most complex supramolecular machines in any eukaryotic cell. The RNA components of a spliceosome are the catalysts of the various splicing steps. The overall complex can be considered a highly flexible ribonucleoprotein enzyme that can adapt to the great diversity in size and sequence of nuclear pre-mRNAs.

Spliceosomal introns generally have the dinucleotide sequence GU at the 5′ end and AG at the 3′ end, marking the sites where splicing occurs. The U1 snRNA contains a sequence complementary to the 5′ splice site (Fig. 26-16b), and the U1 snRNP binds to this region by forming an RNA duplex with the pre-mRNA. A U2 snRNP binds to the 3′ end, also by base-pairing, and identifies the A residue that becomes the nucleophile used during the first transesterification reaction (Fig. 26-14). Addition of a complex of the U4, U5, and U6 snRNPs, called the tri-snRNP, leads to formation of the spliceosome (Fig. 26-16c).

Key parts of the splicing active site found in the U6 snRNA are initially sequestered by base-pairing to parts of U4 snRNA to prevent aberrant cleavage of nontarget phosphodiester bonds. In a process called activation, the U6 and U4 snRNAs must be unwound and separated to expose the active site needed for the first step in splicing. Unwinding of U4 and U6 as well as many other steps in splicing require ATP hydrolysis by a set of eight different ATPases that are part of the splicing machinery.

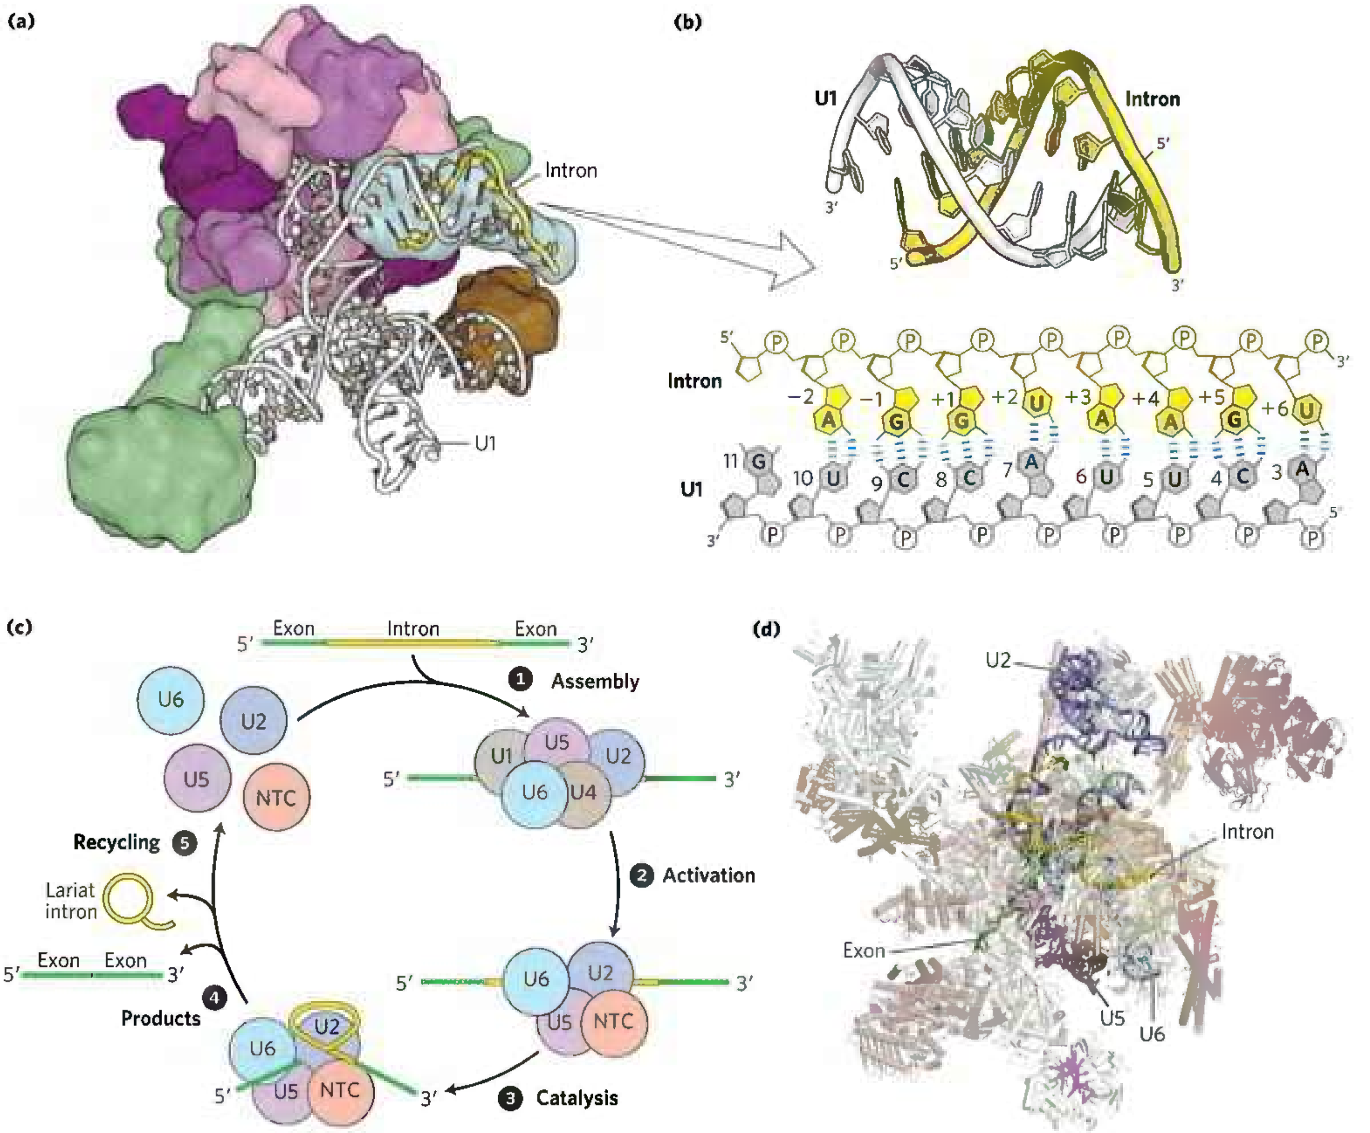

FIGURE 26-16 Processing of pre-mRNA primary transcripts by the spliceosome. (a) Small nuclear RNPs, such as the human U1 snRNP shown here, contain snRNAs associated with a number of proteins. The human U1 snRNP contains a single copy of the U1 snRNA and 10 associated polypeptides. (b) The U1 snRNP recognizes the 5′ splice site by base-pairing between the U1 snRNA and conserved RNA sequences within the intron that mark the 5′ exon/intron boundary. The sequences and structure shown were obtained from x-ray crystal structure shown in (a). The human U1 snRNA normally contains pseudouridines at positions 5 and 6; however, an unmodified RNA was used to determine this structure. (c) Spliceosomes are assembled on introns from snRNPs and proceed through stages of assembly, activation, catalysis of intron removal, release of the RNA products, and recycling of the splicing factors. In addition to the U snRNPs discussed in the text, a large protein-only supramolecular complex called the Prp19-containing complex (also known as NineTeen Complex, or NTC) is required for splicing and joins the spliceosome during the activation step. (d) Structure of the human spliceosome, determined by cryo-EM. Nuclear pre-mRNA splicing requires this large molecular machine composed of dozens of proteins and five snRNAs to remove many different introns. By comparison, using similar chemistry, group II introns can catalyze their own removal. In order to highlight the RNA catalytic core of the spliceosome and the U2, U5, and U6 snRNAs, some protein splicing factors are not shown in this view. The RNA appears discontinuous where the structure could not be resolved. [Data from (a, b) PDB ID 4PJO, Y. Kondo et al., *eLife* 4:e04986, 2015; (d) PDB ID 6QDV, S. Fica et al., *Science* 363:710, 2019.]

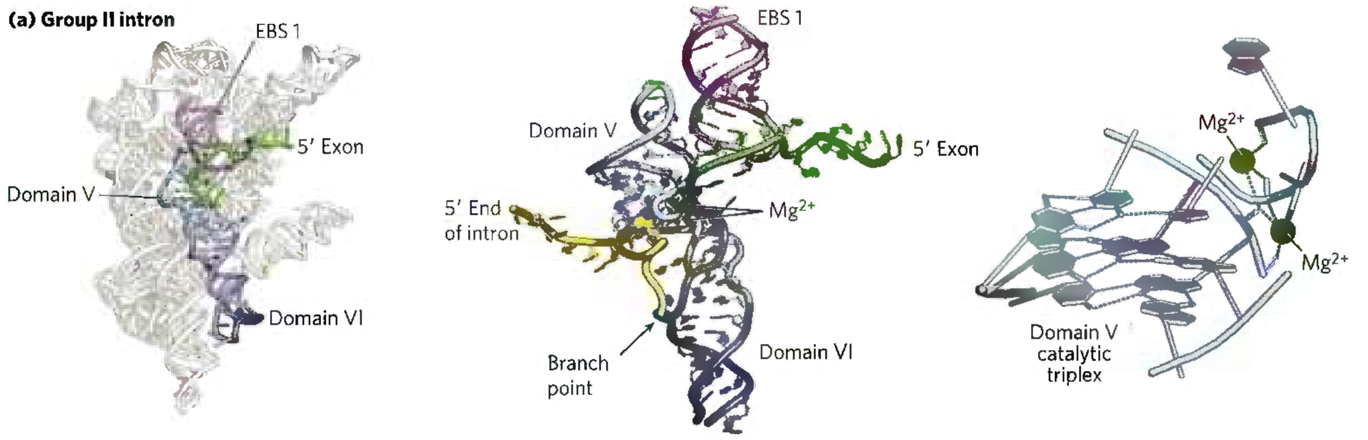
Spliceosomes are single turnover enzymes, meaning that each spliceosome can remove only one intron from a single transcript. As a result, spliceosomes undergo a complex cycle of assembly, activation, catalysis, product release, and recycling of the snRNP components each time an intron is removed (Fig. 26-16c, steps ❶ through ❺).

The chemical events of splicing—5′ splice site cleavage by formation of an intron lariat followed by exon ligation—are identical in mechanism to that of group II introns, despite the former requiring dozens of proteins for activity and the latter being a self-splicing ribozyme. The similarities in chemistry as well as conservation between essential RNA components of each enzyme suggests that group II introns and spliceosomes are evolutionarily related to one another. Comparison of x-ray crystal structures of group II introns and cryo-EM structures of spliceosomes provide strong support for this hypothesis. Despite being surrounded by a large protein scaffold, the catalytic center of the spliceosome is composed of RNA and arranged in a nearly identical manner to that of group II introns (**Fig. 26-17**). Thus, the spliceosome uses a ribozyme core to carry out pre-mRNA splicing. As we shall see, some group II introns also contain domains that are themselves translated as mRNAs and encode proteins that bear striking similarity to those in the spliceosome, strengthening this evolutionary connection.

About 1% of human introns are spliced by a less common type of spliceosome, called the minor spliceosome, in which the U1, U2, U4, and U6 snRNPs are replaced by the U11, U12, U4atac, and U6atac snRNPs. Whereas U1- and U2-containing spliceosomes remove introns with (5′)GU and AG(3′) terminal sequences, the minor spliceosomes remove a rare class of introns that have (5′)AU and AC(3′) terminal sequences to mark the splice sites. Introns removed by either the major or the minor spliceosome most often remain in the nucleus and are degraded.

(a) Group II intron



(b) Spliceosome

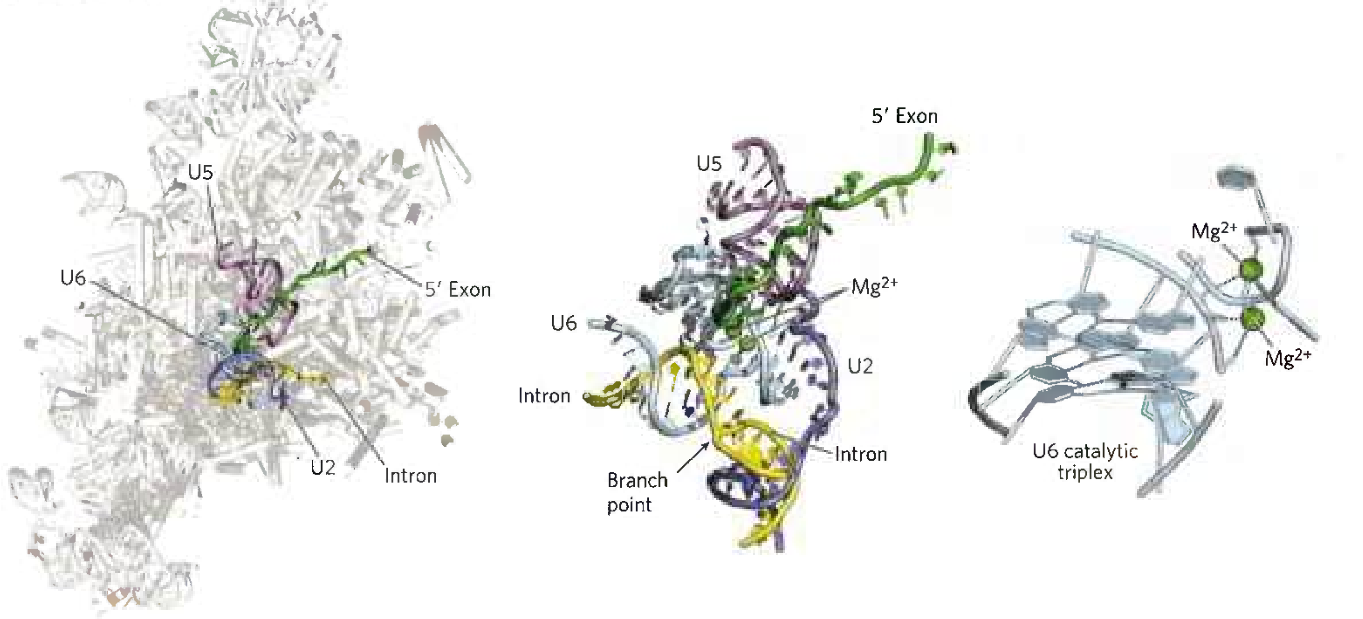


FIGURE 26-17 RNA active site conservation between group II introns and the spliceosome. A close-up examination of the active sites of (a) the *Pylaiella littoralis* group II intron and (b) the *S. cerevisiae* spliceosome reveal a similar arrangement of catalytic RNAs. In both cases, a catalytic RNA (domain V of the group II intron or U6 snRNA of the spliceosome) promotes a transesterification reaction by orienting the phosphodiester bond located at the 5′ splice site/intron junction for nucleophilic attack and by coordinating essential Mg^{2+} ions. In addition to similarities between domain V of group II introns and the U6 snRNA, group II intron domain VI and exon binding site 1 (EBS 1) play functional roles that are similar to those of the U2 and U5 snRNAs in the spliceosome. Close examination shows that the active sites of the group II intron and the spliceosome are nearly identical, formed by a complex arrangement of nucleotides called the catalytic triplex. The triplex is responsible for binding Mg^{2+} ions essential for catalysis as well as orienting the substrates for the splicing reaction. Conservation of sequence, chemistry, and three-dimensional structure suggests that the spliceosome evolved from a group II intron–like ribozyme. [Data from (a) left and center PDB ID 4R0D, A. R. Robart et al., *Nature* 514:193, 2014; right PDB ID 6QDV, S. M. Fica et al., *Science* 363:710, 2019; (b) left PDB ID 5LJ3, W. P. Galej et al., *Nature* 537:197, 2016; center PDB ID 5MQ0, S. M. Some components of the splicing apparatus are tethered to the CTD of RNA polymerase II, indicating that splicing, like other RNA processing reactions, is tightly coordinated with transcription. Most splicing in humans occurs cotranscriptionally, meaning that splicing occurs while Pol II is still transcribing the gene. For this to occur correctly, the rates of transcription, capping, splicing, and 3′ end formation must be carefully regulated. Splicing of a pre-mRNA in the nucleus can also have profound effects on the function of the mRNA in the cytoplasm. Lynne Maquat and Melissa Moore discovered that the human spliceosome leaves behind a set of proteins on each spliced mRNA near the junction between two exons. This exon junction complex is retained on the mRNA as it is exported to the cytoplasm, where it can regulate the extent to which an mRNA can be translated over its lifetime before degradation.

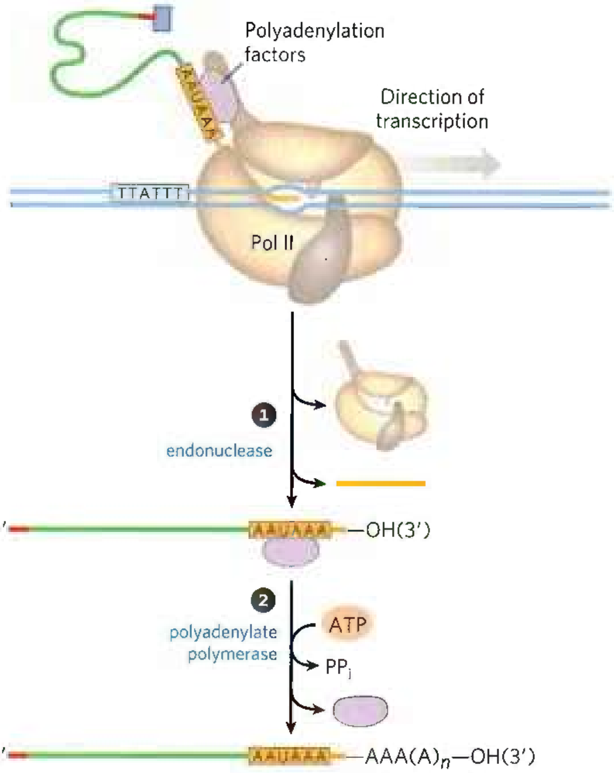

FIGURE 26-18 Addition of the poly(A) tail to the primary RNA transcript of eukaryotes. Pol II synthesizes RNA beyond the segment of the transcript containing the cleavage signal sequences, including the highly conserved upstream sequence (5′)AAUAAA. This cleavage signal sequence is bound by an enzyme complex that includes an endonuclease, a polyadenylate polymerase, and several other multisubunit proteins involved in sequence recognition, stimulation of cleavage, and regulation of the length of the poly(A) tail; all of these proteins are tethered to the CTD. ❶ The RNA is cleaved by the endonuclease at a point 10 to 30 nucleotides 3′ to (downstream of) the sequence AAUAAA. ❷ The polyadenylate polymerase synthesizes a poly(A) tail 80 to 250 nucleotides long, beginning at the cleavage site.

Proteins Catalyze Splicing of tRNAs

A fourth and final class of introns, found in certain tRNAs and a few mRNAs such as XBP1, is distinguished from other intron types in that the splicing reaction requires endonucleases and ligases made of protein and does not involve catalytic RNAs. The splicing endonuclease cleaves the phosphodiester bonds at both ends of the intron, and the two exons are joined by a mechanism similar to the DNA ligase reaction (see Fig. 25-15).

Eukaryotic mRNAs Have a Distinctive 3′ End Structure

P2 At their 3′ end, most eukaryotic mRNAs undergoing translation in the cell cytoplasm have a string of A residues, about 30 residues in yeast and 50 to 100 in animals, called the **poly(A) tail**. This tail serves as a binding site for one or more specific proteins. The poly(A) tail and its associated proteins have a variety of roles in coordinating transcription and translation, and may help protect mRNA from enzymatic destruction. Many bacterial mRNAs also acquire poly(A) tails, but these tails stimulate decay of mRNA rather than protecting it from degradation.

The poly(A) tail is added in a multistep process. The transcript is extended beyond the site where the poly(A) tail is to be added, then is cleaved at the poly(A) addition site by an endonuclease component of a large enzyme complex, again associated with the CTD of RNA polymerase II (Fig. 26-18). The mRNA site where cleavage occurs is marked by two sequence elements: the highly conserved sequence (5′)AAUAAA(3′), 10 to 30 nucleotides on the 5′ side (upstream) of the cleavage site, and a less well-defined sequence rich in G and U residues, 20 to 40 nucleotides downstream of the cleavage site. Cleavage generates the free 3′-hydroxyl group that defines the end of the mRNA, to which A residues are immediately added by **polyadenylate polymerase**, which catalyzes the reaction

$$\text{RNA} + n\text{ATP} \longrightarrow \text{RNA—(AMP)}n + n\text{PP}_i$$

where $n = 80$ to 250. This enzyme does not require a template but does require the cleaved mRNA as a primer. These longer poly(A) tails are added in the nucleus, and then shortened significantly after the mRNA is transported to the cytoplasm.

The overall processing of a typical eukaryotic mRNA is summarized in Figure 26-19. In some cases, the polypeptide-coding region of the mRNA is also modified by RNA "editing" (see Section 27.1 for details). This editing includes processes that add or delete bases in the coding regions of primary transcripts or that change the sequence (such as by enzymatic deamination of a C residue to create a U residue). A particularly dramatic example occurs in trypanosomes, which are parasitic protists: large regions of an mRNA are synthesized without any uridylate, and the U residues are inserted later by RNA editing.

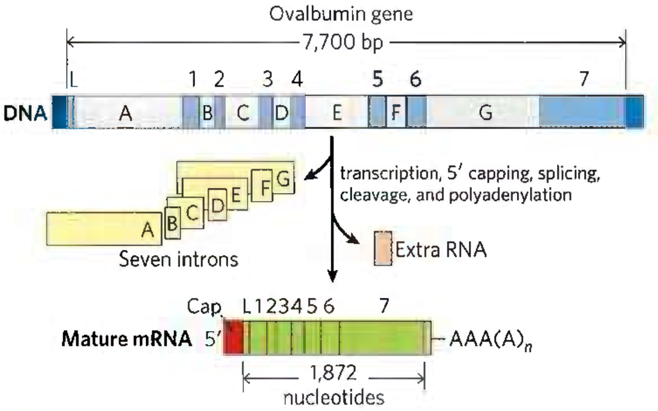

FIGURE 26-19 Overview of the processing of a eukaryotic mRNA. The ovalbumin gene, shown here, has introns A to G and exons 1 to 7 and L (L encodes a signal peptide sequence that targets the protein for export from the cell; see Fig. 27-38). About three-quarters of the RNA is removed during processing. Pol II extends the primary transcript well beyond the cleavage and polyadenylation site ("extra RNA") before terminating transcription.

A Gene Can Give Rise to Multiple Products by Differential RNA Processing

One of the paradoxes of modern genomics is that the apparent complexity of organisms does not correlate with the number of protein-coding genes, or even the amount of genomic DNA. Some eukaryotic mRNA transcripts can be processed in more than one way to produce *different* mRNAs and thus different polypeptides. Much of the variability in processing is the result of **alternative splicing**, in which a particular exon may or may not be incorporated into the mature mRNA transcript. Alternative splicing occurs in a relatively small number of transcripts in yeast, but in more than 95% of human genes. Changes in alternative splicing can have profound impact on the development of an organism (**Box 26-2**). Alternative splicing of a single transcription factor in the staple grain quinoa differentiates palatable sweet varieties from those too bitter to ingest without processing. In *Drosophila*, sex is determined by alternative splicing of the *sex lethal* (*Sxl*) transcript based on the number of X chromosomes present in the cell.

Figure 26-20a illustrates how alternative splicing patterns can produce more than one protein from a common pre-mRNA. The pre-mRNA contains molecular signals for all the alternative processing pathways, and the pathway favored in a given cell or metabolic situation is determined by processing factors, RNA-binding proteins that promote one particular path. For example, splicing regulatory proteins or heterogeneous ribonuclear proteins (hnRNPs) may bind these signals and promote or inhibit spliceosome assembly at that site. There are many additional patterns of alternative splicing.

Complex transcripts can also have more than one site where poly(A) tails can form (Fig. 26-20b). If there are two or more sites for cleavage and polyadenylation, use of the one closest to the 5′ end will remove more of the primary transcript sequence. This mechanism,

BOX 26-2 MEDICINE

Alternative Splicing and Spinal Muscular Atrophy

Alternative splicing is one of the least understood steps in human gene regulation, in part because a gene product can be spliced together in many ways: entire exons can be left out of the mRNA (skipped) or spliced in (retained). More subtle changes can also occur in which alternative 5′ or 3′ splice sites are used that differ from their canonical positions by just a few nucleotides. The spliced isoform that is generated is determined by interactions among the spliceosome, a large number of regulatory factors that associate with the pre-mRNA transcript, and other cellular machinery, including the transcription complex.

Despite this complexity, scientists are learning how to control alternative splicing to treat genetic diseases such as spinal muscular atrophy (SMA). SMA is a progressive neurodegenerative disease and in its most severe form is always fatal. It is the most common genetic cause of death in infants. SMA is caused by a defect in the *SMN1* (survival of motor neuron 1) gene. *SMN1* encodes a protein that is essential for assembly of cellular snRNPs, including those that make up the spliceosome.

Humans have two *SMN* genes: *SMN1* and *SMN2*. However, only *SMN1* is capable of being correctly spliced to produce a functional protein (Fig. 1). *SMN2* encodes an RNA sequence called a silencer, which causes exon 7 to be excluded from the mRNA. As a result, *SMN2* cannot produce functional protein. Healthy individuals are able to get all of the SMN protein they require for snRNP assembly from the *SMN1* gene. But those with a mutation in *SMN1* do not produce enough SMN protein to assemble an adequate number of snRNPs. This leads to neuromuscular degeneration that is often fatal.

One possible solution for treating SMA would be to find a way to change the alternative splicing pattern of the SMN2 gene so that exon 7 would be included rather than skipped. This would produce functional SMN protein. This is exactly the strategy that

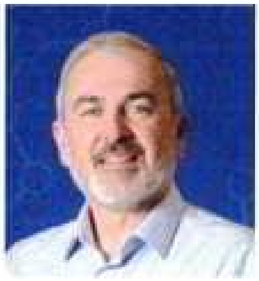
FIGURE 1 Alternative splicing of the *SMN1* and *SMN2* gene transcripts in healthy individuals and in those with SMA. (a) In healthy individuals, active protein is produced by translation of mRNAs that include exon 7 of the *SMN1* gene. Alternative splicing of the *SMN2* transcript skips exon 7, resulting in an mRNA that cannot produce functional protein. (b) In SMA patients, a mutation in the *SMN1* gene results in no functional protein being produced from either *SMN1* or *SMN2*. (c) Upon treatment with nusinersen, alternative splicing of *SMN2* results in an mRNA that includes exon 7 and produces functional protein. This can prevent neuromuscular degeneration. [Information from D. R. Corey, *Nat. Neurosci.* 20:497, 2017, Fig. 1.]



Adrian Krainer [Courtesy Adrian Krainer.]

Adrian Krainer used to correct SMA phenotypes in mice. Scientists in the Krainer lab discovered that if they injected mice with a synthetic oligonucleotide complementary to the silencer sequence of *SMN2* exon 7 (also called an *antisense* oligonucleotide, or ASO), the sequence would be hidden from the splicing machinery. This changes the splicing of the SMN2 gene so that exon 7 is included and the SMN2 gene is able to produce a functional SMN protein and prevent neurodegeneration (Fig. 1).

A drug called nusinersen has since been developed based on Krainer's research and became the first approved treatment for SMA. In SMA patients, injection of nusinersen into the central nervous system can correct splicing of the human *SMN2* gene product, restore SMN protein production, and halt neurodegeneration. Most pharmaceuticals are small, organic molecules, but nusinersen is an 18-mer oligonucleotide. To turn an oligonucleotide into a drug, researchers had to incorporate chemical modifications into the phosphate backbone and ribose sugar (Fig. 2). These modifications prevent the oligonucleotide from being destroyed by cellular nucleases and also improve binding to RNA targets. Currently very few nucleic acid–based drugs have been approved for medical use, but their importance in medicine will likely continue to grow.

called **poly(A) site choice**, generates diversity in the variable domains of immunoglobulin heavy chains (see Fig. 25-42).

Both alternative splicing and poly(A) site choice come into play in the expression of many genes. For example, a single RNA transcript is processed using both mechanisms to produce two different hormones: the calcium-regulating hormone calcitonin in rat thyroid and calcitonin-gene-related peptide (CGRP) in rat brain (**Fig. 26-21**). **P2** Together, alternative splicing and poly(A) site choice greatly increase the variety of proteins generated from the genomes of higher eukaryotes.

FIGURE 26-21 Alternative processing of the calcitonin gene transcript in rats. The calcitonin gene encodes a primary transcript with two poly(A) sites; one predominates in the brain, the other in the thyroid. In the brain, splicing eliminates the calcitonin exon (exon 4); in the thyroid, this exon is retained. The resulting peptides are processed further to yield the final hormone products: calcitonin in the thyroid and calcitonin-gene-related peptide (CGRP) in the brain.

Ribosomal RNAs and tRNAs Also Undergo Processing

Posttranscriptional processing is not limited to mRNA. Ribosomal RNAs of bacterial, archaeal, and eukaryotic cells are made from longer precursors called **pre-ribosomal RNAs**, or pre-rRNAs. Transfer RNAs are similarly derived from longer precursors. These RNAs may also contain a variety of modified nucleosides; some examples are shown in **Figure 26-22**.

Ribosomal RNAs In bacteria, 16S, 23S, and 5S rRNAs (and some tRNAs, although most tRNAs are encoded elsewhere) arise from a single 30S RNA precursor of about 6,500 nucleotides. RNA at both ends of the 30S precursor and segments between the rRNAs are removed during processing (**Fig. 26-23**). The 16S and 23S rRNAs contain modified nucleosides. In *E. coli*, the 11 modifications in the 16S rRNA include a pseudouridine and 10 nucleosides methylated on the base or the 2′-hydroxyl group or both. The 23S rRNA has 10 pseudouridines, 1 dihydrouridine, and 12 methylated nucleosides. In bacteria, each modification is generally catalyzed by a distinct enzyme. Methylation reactions use *S*-adenosylmethionine as cofactor. No cofactor is required for pseudouridine formation.

FIGURE 26-22 Some modified bases of RNA produced in posttranscriptional reactions. The standard symbols are shown in parentheses. This is just a small sampling of the 96 modified nucleosides known to occur in different RNA species, with 81 different types known in tRNAs and 30 observed to date in rRNAs. Notice the unusual ribose attachment point in pseudouridine. A complete listing of these modified bases can be found in the Modomics database of RNA modification pathways (http://iimcb.genesilico.pl/modomics/).

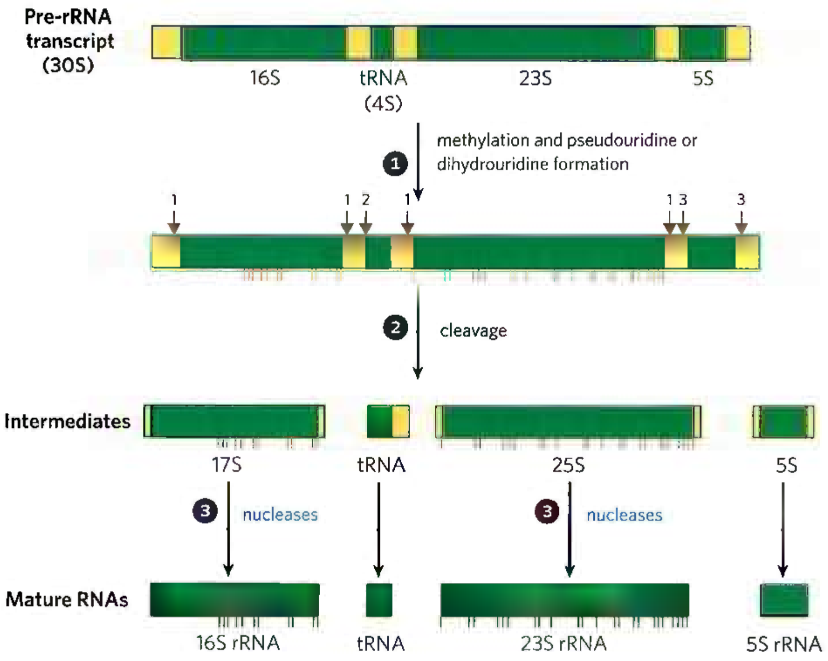

FIGURE 26-23 Processing of pre-rRNA transcripts in bacteria. ❶ Before cleavage, the 30S RNA precursor is methylated at specific bases (red tick marks), and some uridine residues are converted to pseudouridine (blue tick) or dihydrouridine (black tick) residues. The methylation reactions are of multiple types, some occurring on bases and some on 2′-hydroxyl groups. ❷ Cleavage liberates precursors of rRNAs and tRNA(s). Cleavage at the points labeled 1, 2, and 3 is carried out by the enzymes RNase III, RNase P, and RNase E, respectively. As discussed later in the text, RNase P is a ribozyme. ❸ The final 16S, 23S, and 5S rRNA products result from the action of a variety of specific nucleases. The seven copies of pre-rRNA gene in the *E. coli* chromosome differ in the number, location, and identity of tRNAs included in the primary transcript. Some copies of the gene have additional tRNA gene segments between the 16S and 23S rRNA segments and at the far 3′ end of the primary transcript.

The genome of *E. coli* encodes seven pre-rRNA molecules. All of these genes have essentially identical rRNA-coding regions, but they differ in the segments between these regions. The segment between the 16S and 23S rRNA genes generally encodes one or two tRNAs, with different tRNAs produced from different pre-rRNA transcripts. Coding sequences for tRNAs are also found on the 3′ side of the 5S rRNA in some precursor transcripts.

The situation in eukaryotes is even more complicated (see Fig. 27-17). The entire process is initiated in the nucleolus, in large complexes that assemble on the rRNA precursor as it is synthesized by Pol I. There is a tight coupling between rRNA transcription, rRNA maturation, and ribosome assembly in the nucleolus. Each complex includes the ribonucleases that cleave the rRNA precursor, the enzymes that modify particular bases, large numbers of ncRNAs called **small nucleolar RNAs**, or **snoRNAs**, that guide nucleoside modification and some cleavage reactions, and ribosomal proteins. In yeast, the entire process involves the pre-rRNA, more than 170 nonribosomal proteins, snoRNAs for each nucleoside modification (about 70, because some snoRNAs guide two types of modification), and the 78 ribosomal proteins. Humans have an even greater number of modified nucleosides, about 200, and a greater number of associated snoRNAs. The composition of the complexes may change as the ribosomes are assembled, and many of the intermediate complexes rival the ribosome itself in complexity. The 5S rRNA of most eukaryotes is made as a completely separate transcript by a different polymerase (Pol III).

The most common nucleoside modifications in eukaryotic rRNAs are conversion of uridine to pseudouridine and adoMet-dependent nucleoside methylation (often at 2′-hydroxyl groups). These reactions often rely on snoRNA-protein complexes, or **snoRNPs**, each consisting of a snoRNA and four or five proteins, including the enzyme that carries out the modification. There are two classes of snoRNPs, both defined by key conserved sequence elements referred to as lettered boxes. The box H/ACA snoRNPs function in pseudouridylylation, and box C/D snoRNPs in 2′-*O*-methylations. The snoRNAs are 60 to 300 nucleotides long. Each snoRNA includes a 10 to 21 nucleotide sequence that is perfectly complementary to some site on an rRNA and serves to identify the modification site (Fig. 26-24). The conserved sequence elements in the remainder of the snoRNA fold into structures that are bound by the snoRNP proteins.

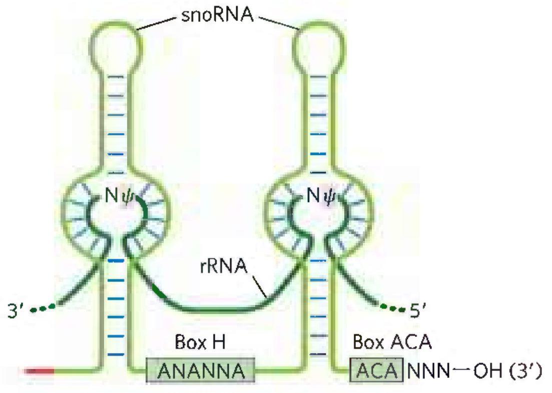

FIGURE 26-24 RNA pairing with box H/ACA snoRNAs to guide pseudouridylations. The pseudouridine conversion sites in the target rRNA are in the regions paired with the snoRNA, and the conserved H/ACA box sequences are protein-binding sites. [Information from T. Kiss, *Cell* 109:145, 2002.]

Transfer RNAs Most cells have 40 to 50 distinct tRNAs, and eukaryotic cells have multiple copies of many of the tRNA genes. Transfer RNAs are derived from longer RNA precursors by enzymatic removal of nucleotides from the 5′ and 3′ ends (**Fig. 26-25**). In eukaryotes, introns are present in a few tRNA transcripts and must be excised. Where two or more different tRNAs are contained in a single primary transcript, they are separated by enzymatic cleavage. The endonuclease RNase P, found in all organisms, removes RNA at the 5′ end of tRNAs. This enzyme contains both protein and RNA. The RNA component is essential for activity, and in bacterial cells it can carry out its processing function with precision even without the protein component. RNase P is another example of a catalytic RNA, as described in more detail below. The 3′ end of tRNAs is processed by one or more nucleases, including the exonuclease RNase D.

Transfer RNA precursors may undergo further post-transcriptional processing. The 3′-terminal trinucleotide CCA(3′) to which an amino acid is attached during protein synthesis (Chapter 27) is absent from some bacterial tRNA precursors and all eukaryotic tRNA precursors and is added during processing (Fig. 26-25). This addition is carried out by tRNA nucleotidyltransferase, an unusual enzyme that binds the three ribonucleoside triphosphate precursors in separate active sites and catalyzes formation of the phosphodiester bonds to produce the CCA(3′) sequence. The creation of this defined sequence of nucleotides is therefore not dependent on a DNA or RNA template—the template is the binding site of the enzyme.

The final type of tRNA processing is the modification of some bases by methylation, deamination, or reduction (Fig. 26-22). These modifications can change how the tRNA interacts with cellular proteins and even how the tRNA is used by the ribosome during translation. In the case of pseudouridine, the base (uracil) is removed and reattached to the sugar through C-5. Some of these modified bases occur at characteristic positions in all tRNAs (Fig. 26-25).

Special-Function RNAs Undergo Several Types of Processing

The number of known classes of special-function noncoding RNAs (ncRNAs) is expanding rapidly, as is the variety of functions known to be associated with them. Many of these ncRNAs also undergo processing.

The snRNAs and snoRNAs not only facilitate RNA processing reactions but also are themselves synthesized as larger precursors and then processed. Many snoRNAs are encoded within the introns of other genes. As the introns are spliced from the pre-mRNA, proteins bind to the snoRNA sequences and ribonucleases remove the extra RNA at the 5′ and 3′ ends to form the snoRNP. The snRNAs destined for spliceosomes are synthesized as pre-snRNAs, and ribonucleases remove the extra RNA at each end. Particular nucleosides in snRNAs are also subject to 11 types of modification, with 2′-*O*-methylation and conversion of uridine to pseudouridine predominating.

MicroRNAs (miRNAs) are a special class of noncoding RNAs involved in gene regulation. The miRNAs are about 22 nucleotides long, complementary in sequence to particular regions of mRNAs. Found in plants and in animals, from worms to mammals, they promote mRNA

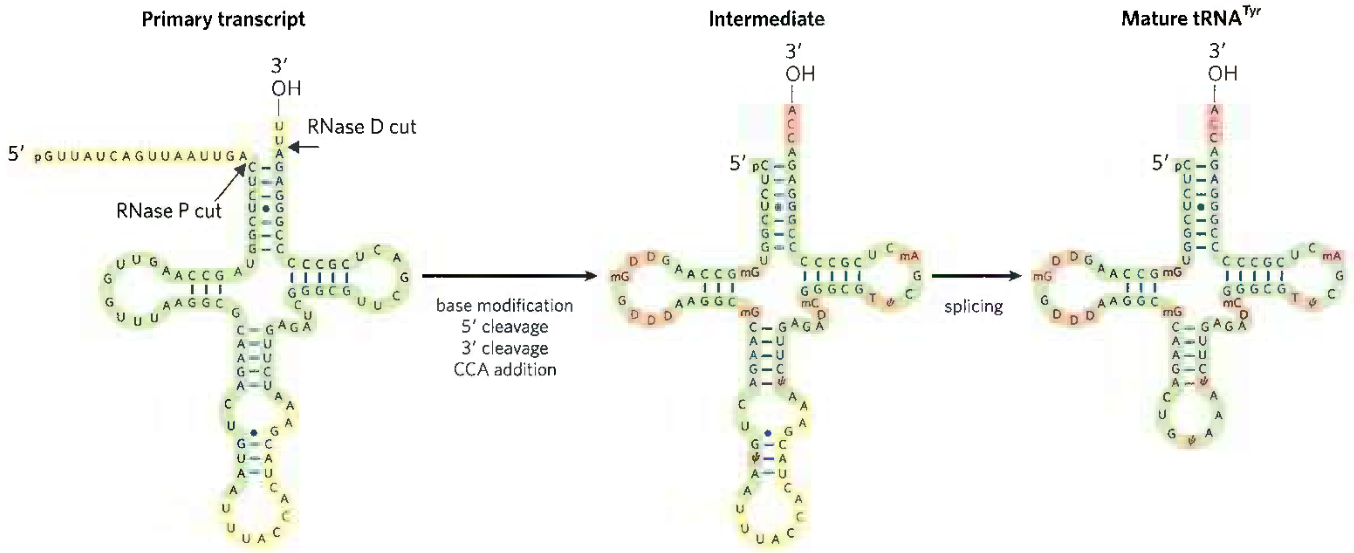

FIGURE 26-25 Processing of tRNAs in bacteria and eukaryotes. The yeast tRNA^{Tyr} (the tRNA specific for tyrosine binding; see Chapter 27) is used to illustrate the important steps. Short blue lines represent normal base pairing; blue dots indicate G–U base pairs. The nucleotide sequences shown in yellow are removed from the primary transcript. The ends are processed first, the 5′ end before the 3′ end. CCA is then added to the 3′ end, a necessary step in processing all eukaryotic tRNAs and for those bacterial tRNAs that lack this sequence in the primary transcript. While the ends are being processed, specific bases in the rest of the transcript are modified (see Fig. 26-22). For the eukaryotic tRNA shown here, the final step is splicing of the 14 nucleotide intron by a protein enzyme. Introns are found in some eukaryotic tRNAs but not in bacterial tRNAs.

degradation and suppress translation to fine-tune gene expression. About 1,500 human genes encode miRNAs, and one or more of these miRNAs affect the expression of most protein-coding genes.

The miRNAs are synthesized from much larger precursors, in several steps (**Fig. 26-26**). The primary transcripts for miRNAs (pri-miRNAs) vary greatly in size; some are encoded in the introns of other genes and are coexpressed with these host genes. Processing of pri-miRNA is mediated by two endoribonucleases in the RNase III family, Drosha and Dicer. First, in the nucleus, the pri-miRNA is reduced to a 70 to 80 nucleotide precursor miRNA (pre-miRNA) by a protein complex including Drosha and another protein, DGCR8. The pre-miRNA is then exported to the cytoplasm in a complex with two proteins, exportin-5 and the Ran GTPase (see Fig. 27-42). In the cytoplasm, Ran hydrolyzes the GTP, then exportin-5 and the pre-miRNA are released. The pre-miRNA is then acted on by Dicer to produce the nearly mature miRNA paired with a short RNA complement. The complement is removed by an RNA helicase, and the mature miRNA is incorporated into protein complexes, such as the RNA-induced silencing complex (RISC), which then bind a target mRNA. If the complementarity between miRNA and its target is nearly perfect, the target mRNA is cleaved. If the complementarity is only partial, the complex blocks translation of the target mRNA. The roles of miRNAs and RISC in gene regulation are detailed in Chapter 28.

Cellular mRNAs Are Degraded at Different Rates

The expression of genes is regulated at many levels. A crucial factor governing a gene's expression is the cellular concentration of its associated mRNA. The concentration of any molecule depends on two factors: its rate of synthesis and its rate of degradation. When synthesis and degradation of an mRNA are balanced, the concentration of the mRNA remains in a steady state. A change in either rate will lead to net accumulation or depletion of the mRNA. **P2** Degradative pathways ensure that mRNAs do not build up in the cell and direct the synthesis of unnecessary proteins.

The rates of degradation vary greatly for mRNAs from different eukaryotic genes. For a gene product that is needed only briefly, the half-life of its mRNA may be only minutes or even seconds. Gene products needed

FIGURE 26-26 **Synthesis and processing of miRNAs.** The primary transcript of miRNAs is a larger RNA of variable length, called pri-miRNA. The pri-miRNA undergoes a number of processing events both in the nucleus and in the cytoplasm to make a mature miRNA. Once the miRNA has been loaded into a protein complex called RISC, it can then hybridize to mRNAs and repress their translation or trigger their cleavage and destruction. [Information from E. Wienholds and R. H. A. Plasterk, *FEBS Lett.* 579:5911, 2005; V. N. Kim et al., *Nat. Rev. Mol. Cell Biol.* 10:126, 2009, Figs 2–4.]

constantly by the cell may have mRNAs that are stable over many cell generations. The average half-life of the mRNAs of a vertebrate cell is about 3 hours, with the pool of each type of mRNA turning over about 10 times per cell generation. The half-life of bacterial mRNAs is much shorter—only about 1.5 min—perhaps because of regulatory requirements.

Messenger RNA is degraded by ribonucleases present in all cells. In *E. coli*, mRNAs typically contain 5′ triphosphates remaining from the initiation of transcription. These groups protect the mRNA from 5′ degradation. As a result, mRNA decay begins with one or several cuts by an endoribonuclease, followed by 3′→5′ degradation by exoribonucleases (**Fig. 26-27**). The initial cut by the endonuclease generates an RNA fragment with a 5′ monophosphate end, which serves to tether the endonuclease to the transcript and ensure its rapid destruction. Some bacteria (*Bacillus subtilis*, for example), have exonucleases that also recognize the 5′ monophosphate end and can degrade RNA fragments in the 5′→3′ direction.

Polynucleotide phosphorylase (PNPase) is a common 3′→5′ exoribonuclease responsible for the degradation of many mRNAs in bacteria, chloroplasts, and mitochondria. It catalyzes the reversible phosphorolysis (rather than hydrolysis) of the mRNA chain using orthophosphate as the nucleophile. The PNPase reaction is readily reversible and the enzyme can also add nucleotides to the 3′ ends of bacterial mRNAs. Decay of mRNAs containing complex 3′ end structures, such as the hairpins responsible for ρ-independent transcription termination (see Fig. 26-7), can involve multiple rounds of lengthening and shortening of the mRNA by PNPase until it is finally consumed. This unusual nontemplated RNA polymerization activity of PNPase proved to be critical for production of mRNA polymers used for deciphering the genetic code (Chapter 27).

FIGURE 26-27 Degradation of RNA in bacteria. In bacteria, mRNA degradation usually begins by endonucleolytic cleavage because the 5′ and 3′ ends of the mRNA are often protected by a triphosphate and hairpin structure, respectively. In *E. coli*, the RNase E endonuclease carries out this cleavage, whereas in *B. subtilis* the cleavage is carried out by the RNase Y endonuclease. The endonuclease activity produces RNA fragments that serve as substrates for 3′→5′ or 5′→3′ exonucleases. All bacteria contain 3′→5′ exonucleases such as PNPase, RNase R, or RNase II. Some species, like *B. subtilis*, also contain a 5′→3′ exonuclease called RNase J. The 5′ phosphate produced by the endonuclease after the first cleavage can also serve as a tether to link the RNase E endonuclease directly to the mRNA, ensuring its rapid destruction. [Information from M. Hui et al. *Annu. Rev. Genet.* 48:537, 2014.]

As we have previously seen with transcription and RNA processing, the analogous processes for RNA degradation in eukaryotes are much more complex than their bacterial counterparts. Eukaryotes have multiple pathways for mRNA decay, and the pathway used can depend on the mRNA location, its structure, its association with ribosomes, and other factors. However, in most cases, decapping the 5′ end and shortening the 3′ poly(A) tail are critical steps for allowing exonucleases to access the mRNA.

All eukaryotes also have large 3′→5′ exoribonucleases called **exosomes**, which are responsible for the degradation for nearly all types of RNA. Exosomes are multisubunit complexes containing about 10 proteins. Specialized exosomes exist in the nucleus, cytoplasm, and nucleolus. The core of the exosome is a barrel-like structure through which RNA is threaded (**Fig. 26-28**). Even though this core

FIGURE 26-28 Essential role of the exosome in eukaryotic RNA degradation. (a) Exosomes are multisubunit enzymes in which RNA is threaded through a central barrel and fed into a nuclease. In this structure, the exosome core is topped by ATPase and RNA helicase modules that help unwind RNA secondary structures so that single-stranded RNA can pass into the core. Below the core is a nuclease responsible for cleaving the RNA. (b) In this cartoon schematic, the passage of the substrate RNA through the barrel-like exosome and to the nuclease is highlighted. [Data from PDB ID 4IFD, D. L. Makino et al., *Nature* 495:70, 2013; PDB ID 4OO1, E. V. Wasmuth et al., *Nature* 511:435, 2014. Information from K. Januszyk and C. D. Lima, *Curr. Opin. Struct. Biol.* 24:132, 2014.]

is structurally similar to bacterial PNPase, RNA is not degraded within the barrel. Instead, the barrel serves as an adapter that efficiently channels the RNA to associated enzymes with 3′→5′ exonuclease and endonuclease activity.

SUMMARY 26.2 ***RNA Processing***

- Many primary transcripts produced in bacteria and eukaryotes must be processed into a mature form to be functional. Processing can include modifications to the 5′ and 3′ ends of the RNA, removal of internal RNA sequences by splicing, and modifications of the RNA nucleotides.
- Eukaryotic mRNAs have an inverted 7-methylguanosine residue cap at their 5′ end. The cap helps to protect the RNA from degradation and interacts with proteins important for cellular transport and translation.
- Many organisms contain genes in which the coding information is interrupted by introns. Splicing removes these introns and joins the flanking exons. Nearly every human gene contains multiple introns, which can vary dramatically in size.
- There are four classes of introns: group I, group II, spliceosome-processed introns, and protein-processed introns. Group I and II introns are self-splicing with RNAs capable of carrying out catalysis independent of protein enzymes. Catalytic RNAs share features in common with protein-based enzymes.
- Nuclear-encoded introns in eukaryotes are removed by a large RNP machine called a spliceosome. A spliceosome is a single-turnover enzyme containing snRNA and protein that recognizes introns by base-pairing with the snRNAs. Even though a spliceosome contains dozens of proteins, it uses an RNA active site and mechanism similar to that of group II introns.
- Some tRNAs and a few mRNAs contain introns that must be removed by protein-based endonuclease and ligase enzymes.
- In eukaryotes, transcription terminates when an endonuclease cleaves the nascent RNA, freeing it from Pol II. A poly(A) tail is then added to the 3′ end of the RNA by a polyadenylate polymerase.
- Alternative splicing and alternative poly(A) site choice in eukaryotes allow for many different transcripts to be produced from a single gene.
- The primary transcripts of tRNAs, rRNAs, and miRNAs also undergo extensive processing, including endonucleolytic cleavage and chemical modification. Correct placement of these modifications is often guided by snoRNAs that base-pair with the target RNA.
- The cellular lifetime of RNAs can be highly variable, and RNA degradation is tightly regulated. In bacteria, endonucleases generate mRNA fragments for destruction by exonucleases. In eukaryotes, mRNAs typically must be decapped and the poly(A) tail shortened before degradation. The exosome is a supramolecular complex of 3′→5′ exo- and endonucleases involved in many steps of eukaryotic RNA decay.

26.3 RNA-Dependent Synthesis of RNA and DNA

In our discussion of DNA and RNA synthesis up to this point, the role of the template strand has been reserved for DNA. However, some enzymes use an RNA template for nucleic acid synthesis. With the important exception of viruses with an RNA genome, these enzymes play only supporting roles in information pathways. RNA viruses are the source of most characterized RNA-dependent polymerases, although some eukaryotes also use these enzymes to amplify double-stranded RNAs used in RNA interference.

The existence of RNA replication requires an elaboration of the central dogma—the notion that genetic information flows only from DNA to RNA to proteins. RNA-dependent polymerases allow the genetic information stored in RNA to be replicated and reverse transcribed into DNA. The enzymes of the RNA replication process have profound implications for investigations into the nature of self-replicating molecules that may have existed in prebiotic times.

Reverse Transcriptase Produces DNA from Viral RNA

P3 Certain RNA viruses that infect animal cells carry within the viral particle an RNA-dependent DNA polymerase called **reverse transcriptase**. On infection, the single-stranded RNA viral genome (~10,000 nucleotides) and the enzyme enter the host cell. The reverse transcriptase first catalyzes the synthesis of a DNA strand complementary to the viral RNA (**Fig. 26-29**), then degrades the RNA strand of the viral RNA-DNA hybrid and replaces it with DNA. The resulting duplex DNA often becomes incorporated into the genome of the eukaryotic host cell. These integrated (and dormant) viral genes can be activated and transcribed, and the gene products—viral proteins and the viral RNA genome itself—are packaged as new viruses. The RNA viruses that contain reverse transcriptases are known as **retroviruses** (*retro* is the Latin prefix for "backward").

The existence of reverse transcriptases in RNA viruses was predicted by Howard Temin in 1962, and the enzymes were ultimately detected by Temin and, independently, by David Baltimore in 1970. P3 Their discovery aroused much attention as dogma-shaking proof that genetic information can flow "backward" from RNA to DNA.

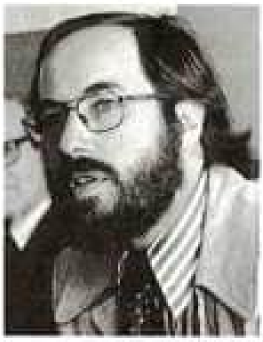
FIGURE 26-29 Retroviral infection of a mammalian cell and integration of the retrovirus into the host chromosome. Viral particles entering the host cell carry viral reverse transcriptase and a cellular tRNA (picked up from a former host cell) already base-paired to the viral RNA. The purple segments represent the long terminal repeats on the viral RNA. The tRNA facilitates immediate conversion of viral RNA to double-stranded DNA by the action of reverse transcriptase. The double-stranded DNA enters the nucleus and is integrated into the host genome. The integration is catalyzed by a virally encoded integrase. Integration of viral DNA into host DNA is mechanistically similar to the insertion of transposons in bacterial chromosomes (see Fig. 25-41). For example, a few base pairs of host DNA become duplicated at the site of integration, forming short repeats of 4 to 6 bp at each end of the inserted retroviral DNA (not shown). On transcription and translation of the integrated viral DNA, new viruses are formed and released by cell lysis (right). In the viruses, the viral RNA is enclosed by capsid proteins called Gag and outer envelope proteins called Env. Additional viral proteins (reverse transcriptase, integrase, and a viral protease needed for posttranslational processing of viral proteins) are packaged within the virus particle with the RNA.

Howard Temin, 1934–1994
[Bettmann/Getty Images]



David Baltimore [AP Images]

Retroviruses typically have three genes: *gag* (a name derived from the historical designation *g*roup *a*ssociated anti*g*en), *pol*, and *env* (**Fig. 26-30**). The transcript that contains *gag* and *pol* is translated into a long "polyprotein," a single large polypeptide that is cleaved into six proteins with distinct functions. The proteins derived from the *gag* gene make up the interior core of the viral particle. The *pol* gene encodes the protease that cleaves the long polypeptide, an integrase that inserts the viral DNA into the host chromosomes, and reverse transcriptase. Many reverse transcriptases have two subunits, α and β. The *pol* gene specifies the β subunit (M_r 90,000), and the α subunit (M_r 65,000) is simply a proteolytic fragment of the β subunit. The *env* gene encodes the proteins of the viral envelope. At each end of the linear RNA genome are long terminal repeat (LTR) sequences of a few hundred nucleotides. Transcribed into the duplex DNA, these sequences facilitate integration of the viral chromosome into the host DNA and contain promoters for viral gene expression.

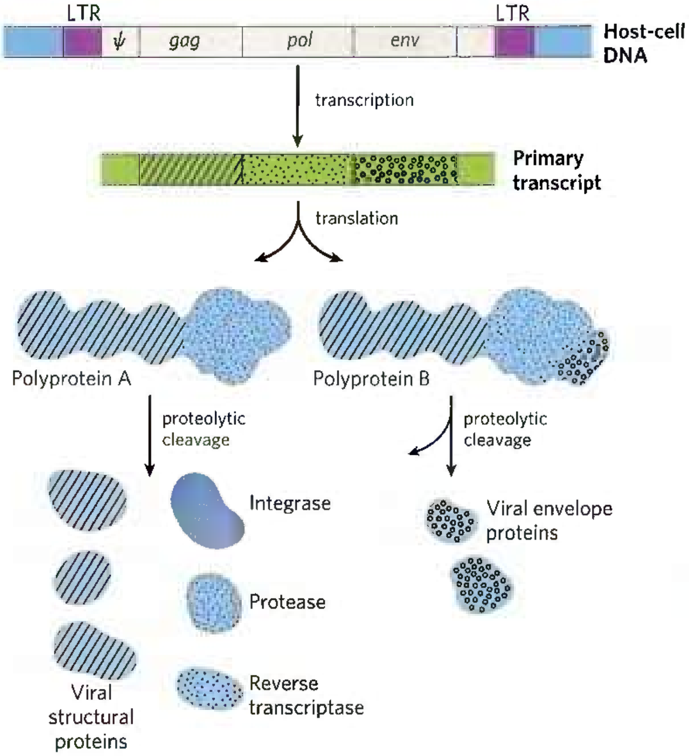


FIGURE 26-30 Structure and gene products of an integrated retroviral genome. The long terminal repeats (LTRs) have sequences needed for the regulation and initiation of transcription. The sequence denoted ψ is required for packaging of retroviral RNAs into mature viral particles. Transcription of the retroviral DNA produces a primary transcript encompassing the *gag*, *pol*, and *env* genes. Translation (Chapter 27) produces a polyprotein, a single long polypeptide derived from the *gag* and *pol* genes, which is cleaved into six distinct proteins. Splicing of the primary transcript yields an mRNA derived largely from the *env* gene, which is also translated into a polyprotein, then cleaved to generate viral envelope proteins.

Reverse transcriptases catalyze three different reactions: (1) RNA-dependent DNA synthesis, (2) RNA degradation, and (3) DNA-dependent DNA synthesis. Each transcriptase is most active with the RNA of its own virus, but each can be used experimentally to make DNA complementary to a variety of RNAs. The DNA and RNA synthesis and RNA degradation activities use separate active sites on the protein. For DNA synthesis to begin, the reverse transcriptase requires a primer, a cellular tRNA obtained during an earlier infection and carried in the viral particle. This tRNA is base-paired at its 3′ end with a complementary sequence in the viral RNA. The new DNA strand is synthesized in the 5′→3′ direction, as in all RNA and DNA polymerase reactions. Reverse transcriptases, like RNA polymerases, do not have 3′→5′ proofreading exonucleases. They generally have error rates of about 1 per 20,000 nucleotides added. An error rate this high is extremely unusual in DNA replication and seems to be a characteristic of most enzymes that replicate the genomes of RNA viruses. A consequence is a higher mutation rate and a faster rate of viral evolution, which is a factor in the frequent appearance of new strains of disease-causing retroviruses.

Reverse transcriptases have become important reagents in the study of DNA-RNA relationships and in DNA cloning techniques. They make possible the synthesis of DNA complementary to an mRNA template, and synthetic DNA prepared in this manner, called **complementary DNA (cDNA)**, can be used to clone cellular genes (see Fig. 9-13).

Some Retroviruses Cause Cancer and AIDS

P3 Retroviruses have featured prominently in the molecular understanding of cancer. Most retroviruses do not kill their host cells but remain integrated in the cellular DNA, replicating when the cell divides. Some retroviruses, classified as RNA tumor viruses, contain an oncogene that can cause the cell to grow abnormally. The first retrovirus of this type to be studied was the Rous sarcoma virus (also called avian sarcoma virus; **Fig. 26-31**), named for F. Peyton Rous, who studied chicken tumors now known to be caused by this virus. Since the initial discovery of oncogenes by Harold Varmus and Michael Bishop, many dozens of such genes have been found in retroviruses.

P3 The human immunodeficiency virus (HIV), which causes acquired immune deficiency syndrome (AIDS), is a retrovirus. Identified in 1983, HIV has an RNA genome with standard retroviral genes along with several other unusual genes (**Fig. 26-32**). Unlike many other retroviruses, HIV kills many of the cells it infects (principally T lymphocytes) rather than causing tumor formation. This gradually leads to suppression of the immune system in the host organism. The reverse transcriptase of HIV is even more error-prone than other known reverse transcriptases — 10 times more so — resulting in high mutation rates in this virus. One or more errors are generally made every time the viral genome is replicated, so any two viral RNA molecules are likely to differ.

Many modern vaccines for viral infections consist of one or more coat proteins of the virus, produced by methods described in Chapter 9. These proteins are not infectious on their own but stimulate the immune

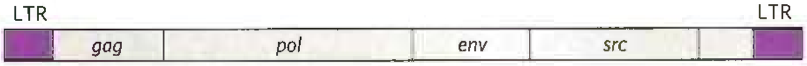

FIGURE 26-31 Rous sarcoma virus genome. The *src* gene encodes a tyrosine kinase, one of a class of enzymes that function in systems affecting cell division, cell-cell interactions, and intercellular communication (see Section 12.4). The same gene is found in chicken DNA (the usual host for this virus) and in the genomes of many other eukaryotes, including humans. When associated with the Rous sarcoma virus, this oncogene is often expressed at abnormally high levels, contributing to unregulated cell division and cancer.

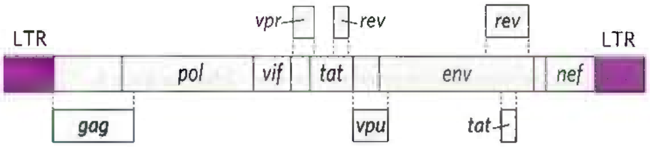

FIGURE 26-32 The genome of HIV, the virus that causes AIDS. In addition to the typical retroviral genes, HIV contains several small genes with a variety of functions (not identified here and not all known). Some of these genes overlap. Alternative splicing mechanisms produce many different proteins from this small (9.7×10^3 nucleotides) genome.

system to recognize and resist subsequent viral invasions (Chapter 5). Because of the high error rate of the HIV reverse transcriptase, the *env* gene in this virus (along with the rest of the genome) undergoes very rapid mutation, complicating the development of an effective vaccine. However, repeated cycles of cell invasion and replication are needed to propagate an HIV infection, so inhibition of viral enzymes offers the most effective therapy currently available. The HIV protease is targeted by a class of drugs called protease inhibitors (see Fig. 6-29). Reverse transcriptase is the target of some additional drugs widely used to treat HIV-infected individuals (**Box 26-3**). ■

Many Transposons, Retroviruses, and Introns May Have a Common Evolutionary Origin

Some well-characterized eukaryotic DNA transposons from sources as diverse as yeast and fruit flies have a structure very similar to that of retroviruses; these are sometimes called retrotransposons (**Fig. 26-33**). Retrotransposons

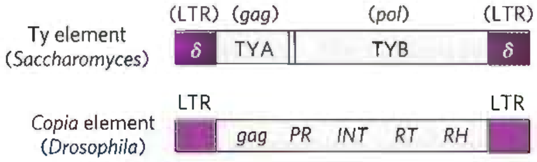

FIGURE 26-33 Eukaryotic transposons. The Ty element of the yeast *Saccharomyces* and the *copia* element of the fruit fly *Drosophila* are examples of eukaryotic retrotransposons, which often have a structure similar to retroviruses but lack the *env* gene. The δ sequences of the Ty element are functionally equivalent to retroviral LTRs. In the *copia* element, *INT* and *RT* are homologous to the integrase and reverse transcriptase segments, respectively, of the *pol* gene.

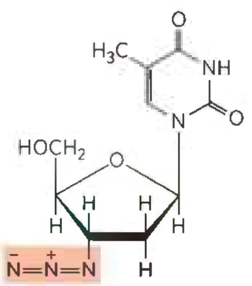
BOX 26-3 MEDICINE

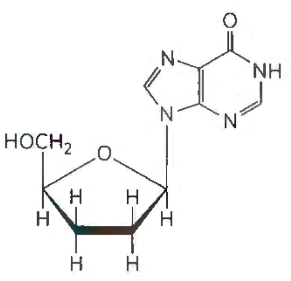
Fighting AIDS with Inhibitors of HIV Reverse Transcriptase

Research into the chemistry of template-dependent nucleic acid biosynthesis, combined with modern techniques of molecular biology, has elucidated the life cycle and structure of the human immunodeficiency virus, the retrovirus that causes AIDS. A few years after the isolation of HIV, this research resulted in the development of drugs capable of prolonging the lives of people infected by HIV.

The first drug to be approved for clinical use was azidothymidine (AZT), a structural analog of deoxythymidine. AZT was first synthesized in 1964 by Jerome P. Horwitz. It failed as an anticancer drug (the purpose for which it was made), but in 1985 it was found to be a useful treatment for AIDS. AZT is taken up by T lymphocytes, immune system cells that are particularly vulnerable to HIV infection, and it is converted to AZT triphosphate. (AZT triphosphate taken directly would be ineffective because it cannot cross the plasma membrane.) HIV's reverse transcriptase has a higher affinity for AZT triphosphate than for deoxythymidine triphosphate (dTTP), and binding of AZT triphosphate to this enzyme competitively inhibits dTTP binding. When AZT is added to the 3′ end of the growing DNA strand, lack of a 3′ hydroxyl means that the DNA strand is terminated prematurely and viral DNA synthesis grinds to a halt.



3′-Azido-2′,3′-dideoxythymidine (AZT)



2′,3′-Dideoxyinosine (DDI)

AZT triphosphate is not as toxic to the T lymphocytes themselves because *cellular* DNA polymerases have a lower affinity for this compound than for dTTP. At concentrations of 1 to 5 μM, AZT affects HIV reverse transcription but not most cellular DNA replication. Unfortunately, AZT seems to be toxic to the bone marrow cells that are the progenitors of erythrocytes, and many individuals taking AZT develop anemia. AZT can increase the survival time of people with advanced AIDS by about a year, and it delays the onset of AIDS in those who are still in the early stages of HIV infection. Some other AIDS drugs, such as dideoxyinosine (DDI), have a similar mechanism of action. Newer drugs target and inactivate the HIV protease. Because of the high error rate of HIV reverse transcriptase and the resulting rapid evolution of HIV, the most effective treatments of HIV infection use a combination of drugs directed at both the protease and the reverse transcriptase.

encode an enzyme homologous to the retroviral reverse transcriptase, and their coding regions are flanked by LTR sequences. They transpose from one position to another in the cellular genome by means of an RNA intermediate, using reverse transcriptase to make a DNA copy of the RNA, followed by integration of the DNA at a new site. Most transposons in eukaryotes use this mechanism for transposition, distinguishing them from bacterial transposons, which move as DNA directly from one chromosomal location to another (see Fig. 25-41).

Retrotransposons lack an *env* gene and so cannot form viral particles. They can be thought of as defective viruses, trapped in cells. Comparisons between retroviruses and eukaryotic transposons suggest that reverse transcriptase is an ancient enzyme that predates the evolution of multicellular organisms.

Many group I and group II introns are also mobile genetic elements. In addition to their self-splicing activities, they encode DNA endonucleases that promote their movement. During genetic exchanges between cells of the same species, or when DNA is introduced into a cell by parasites or by other means, these endonucleases promote insertion of the intron into an identical site in another DNA copy of a homologous gene that does not contain the intron, in a process termed **homing** (**Fig. 26-34**). Whereas group I intron homing is DNA-based, group II intron homing occurs through an RNA intermediate. The endonucleases of the group II introns have associated reverse transcriptase activity. The proteins can form complexes with the intron RNAs themselves, after the introns are spliced from the primary transcripts. Because the homing process involves insertion of the RNA intron into DNA and reverse transcription of the intron, the movement of these introns has been called retrohoming. Over time, every copy of a particular gene in a population may acquire the intron.

FIGURE 26-34 Introns that move: homing and retrohoming. Certain introns include a gene (shown in red) for enzymes that promote homing (some group I introns) or retrohoming (some group II introns). (a) The gene in the spliced intron is bound by a ribosome and translated. Group I homing introns specify a site-specific endonuclease, called a homing endonuclease. Group II retrohoming introns specify a protein with both endonuclease and reverse transcriptase activities (not shown here). (b) Homing. Allele *a* of a gene *X* containing a group I homing intron is present in a cell containing allele *b* of the same gene, which lacks the intron. The homing endonuclease produced by *a* cleaves *b* at the position corresponding to the intron in *a*, and double-strand break repair (recombination with allele *a*; see Fig. 25-34) then creates a new copy of the intron in *b*. (c) Retrohoming. Allele *a* of gene *Y* contains a retrohoming group II intron; allele *b* lacks the intron. The spliced intron inserts itself into the coding strand of *b* in a reaction that is the reverse of the splicing that excised the intron from the primary transcript (see Fig. 26-14), except that here the insertion is into DNA rather than RNA. The noncoding DNA strand of *b* is then cleaved by the intron-encoded endonuclease/reverse transcriptase. This same enzyme uses the inserted RNA as a template to synthesize a complementary DNA strand. The RNA is then degraded by cellular ribonucleases and replaced with DNA.

Much more rarely, the intron may insert itself into a new location in an unrelated gene. If this event does not kill the host cell, it can lead to the evolution and distribution of an intron in a new location. The structures and mechanisms used by mobile introns support the idea that at least some introns originated as molecular parasites whose evolutionary past can be traced to retroviruses and transposons.

Telomerase Is a Specialized Reverse Transcriptase

Telomeres, the structures at the ends of linear eukaryotic chromosomes (see Fig. 24-7), generally consist of many tandem copies of a short oligonucleotide sequence. This sequence usually has the form T_xG_y in one strand and C_yA_x in the complementary strand, where x and y are typically in the range of 1 to 4 (p. 890). Telomeres vary in length from a few dozen base pairs in some ciliated protozoans to tens of thousands of base pairs in mammals. The TG strand is longer than its complement, leaving a region of single-stranded DNA of up to a few hundred nucleotides at the 3′ end.

The ends of a linear chromosome are not readily replicated by cellular DNA polymerases. DNA replication requires a template and primer, and beyond the end of a linear DNA molecule no template is available for the pairing of an RNA primer. Without a special mechanism for replicating the ends, chromosomes would be shortened somewhat in each cell generation. The enzyme **telomerase**, discovered by Carol Greider and Elizabeth Blackburn, solves this problem by adding telomeres to chromosome ends.

Carol Greider [Courtesy Carol Greider.]

Elizabeth Blackburn [Micheline Pelletier/Getty Images.]

The discovery and purification of this enzyme provided insight into a reaction mechanism that is remarkable and unprecedented. Telomerase, like some other enzymes described in this chapter, is an RNP that contains both RNA and protein components. The RNA component in humans is about 150 nucleotides long and contains about 1.5 copies of the appropriate C_yA_x telomere repeat. This region of the RNA acts as a template for synthesis of the T_xG_y strand of the telomere. P3 Telomerase thereby acts as a cellular reverse transcriptase that provides the active site for RNA-dependent DNA synthesis. Unlike retroviral reverse transcriptases, telomerase copies only a small segment of RNA that it carries within itself. Telomere synthesis requires the 3′ end of a chromosome as primer and proceeds in the usual 5′→3′ direction. Having synthesized one copy of the repeat, the enzyme repositions to resume extension of the telomere (**Fig. 26-35a**).

After extension of the T_xG_y strand by telomerase, the complementary C_yA_x strand is synthesized by cellular DNA polymerases, starting with an RNA primer (see Fig. 25-11). The single-stranded region is protected by specific binding proteins in many lower eukaryotes, especially those species with telomeres of less than a few hundred base pairs. In higher eukaryotes (including mammals) with telomeres many thousands of base pairs long, the single-stranded end is sequestered in a specialized structure called a **T loop** (Fig. 26-35b). The single-stranded end is folded back and paired with its complement in the double-stranded portion of the telomere. The formation of a T loop involves invasion of the 3′ end of the telomere's single strand into the duplex DNA, perhaps by a mechanism similar to the initiation of homologous genetic recombination (see Fig. 25-34). In mammals, the looped DNA is bound by two proteins, TRF1 and TRF2, with the latter protein involved in formation of the T loop. T loops protect the 3′ ends of chromosomes, making them inaccessible to nucleases and the enzymes that repair double-strand breaks.

In protozoans (such as *Tetrahymena*), loss of telomerase activity results in a gradual shortening of telomeres with each cell division, ultimately leading to the death of the cell line. A similar link between telomere length and cell senescence (cessation of cell division) has been observed in humans. In germ-line cells, which contain telomerase activity, telomere lengths are maintained; in somatic cells, which lack telomerase, they are not. There is a linear, inverse relationship between the length of telomeres in cultured fibroblasts and the age of the individual from whom the fibroblasts were taken: telomeres in human somatic cells gradually shorten as an individual ages. If the telomerase reverse transcriptase is introduced into human somatic cells in vitro, telomerase activity is restored and the cellular life span increases markedly.

Is the gradual shortening of telomeres a key to the aging process? Is our natural life span determined by the length of the telomeres we are born with? Further research in this area should yield some fascinating insights.

Some RNAs Are Replicated by RNA-Dependent RNA Polymerase

Apart from the retroviruses, the RNA viruses include some *E. coli* bacteriophages as well as eukaryotic viruses such as the influenza virus and coronaviruses that cause SARS or COVID-19. The single-stranded RNA

chromosomes of these viruses also function as mRNAs for the synthesis of viral proteins. They are replicated in the host cell by an **RNA-dependent RNA polymerase (RNA replicase)**. All RNA viruses—with the exception of retroviruses—must encode a protein with RNA-dependent RNA polymerase activity, either because the host cells lack such an enzyme or because the RNA genome structure of a virus imposes specialized enzymatic requirements.

The RNA replicase isolated from *E. coli* cells infected with the bacteriophage Qβ catalyzes the formation of an RNA complementary to the viral RNA, in a reaction equivalent to that catalyzed by DNA-dependent RNA polymerases. New RNA strand synthesis proceeds in the 5′→3′ direction by a chemical mechanism identical to that used in all other nucleic acid synthetic reactions that require a template. RNA replicase requires RNA as its template and will not function with DNA. It lacks

FIGURE 26-36 Structural similarities between RNA-dependent polymerases. RNA-dependent polymerases use a common active site architecture in which the duplexed substrate sits in a hand-shaped protein fold with palm and finger domains. This protein fold can be found in protein factors involved in (a) group II intron retrohoming, (b) spliceosome-catalyzed pre-mRNA splicing, (c) telomere synthesis, (d) HIV reverse transcription, and (e) hepatitis C viral genome replication. The retrohoming reverse transcriptase of group II introns is most structurally related to the reverse transcriptase structure present in the spliceosome, supporting their close evolutionary relationship. [Information from C. Zhao and A. M. Pyle, *Nat. Struct. Mol. Biol.* 23:558, 2016, Fig. 2. Data from (a) PDB ID 5HHJ, C. Zhao and A. M. Pyle, *Nat. Struct. Mol. a separate proofreading endonuclease activity and has an error rate similar to that of RNA polymerase. Unlike the DNA and RNA polymerases, RNA replicases are specific for the RNA of their own virus; the RNAs of the host cell are generally not replicated. This explains how RNA viruses are preferentially replicated in the host cell, which contains many other types of RNA.

RNA-dependent RNA polymerases are not limited to viruses. Enzymes of this type are found in plants, protists, fungi, and some simpler animals, but not in insects or mammals. Those found in the genomes of eukaryotes generally play a role in the metabolism of another class of small RNAs, called small interfering RNAs (siRNAs), which participate in gene regulation (Chapter 28).

RNA-Dependent RNA Polymerases Share a Common Structural Fold

Even though viral RNA replication and reverse transcription, retrohoming, and telomere synthesis represent a diverse array of biological processes, the polymerases involved in each pathway bear remarkable similarities in structure (**Fig. 26-36**). In all cases, palm and finger domains are used to grip the duplexed template and primer nucleic acids within the active site. Amazingly, the group II intron retrohoming reverse transcriptase is structurally most closely related to a protein component of the spliceosome that helps scaffold its RNA active site. In addition to identical splicing chemistry and active site features (see Fig. 26-17), this provides further evidence that the spliceosome evolved from a group II intron–like ancestor.

SUMMARY 26.3 *RNA-Dependent Synthesis of RNA and DNA*

- RNA-dependent DNA polymerases, also called reverse transcriptases, were first discovered in retroviruses, which must convert their RNA genomes into double-stranded DNA as part of their life cycle. These enzymes transcribe the viral RNA into DNA, a process that can be used experimentally to form cDNA.
- Retroviruses can cause human diseases, including AIDS and cancers. Some of these viruses contain oncogenes, which cause infected cells to grow abnormally.
- Many eukaryotic transposons are related to retroviruses, and their mechanism of transposition includes an RNA intermediate. An RNA intermediate is also present in group II intron retrohoming, in which the RNA intron is inserted into a DNA gene followed by production of a DNA copy by a reverse transcriptase.
- Telomerase, the enzyme that synthesizes the telomere ends of linear chromosomes, is a specialized reverse transcriptase that contains an internal RNA template.
- RNA-dependent RNA polymerases, such as the replicases of RNA bacteriophages, are template-specific for the viral RNA. These enzymes share structural homology with reverse transcriptases involved in retroviral replication, telomere production, and retrohoming.

26.4 Catalytic RNAs and the RNA World Hypothesis

P4 The study of posttranscriptional processing of RNA molecules led to one of the most exciting discoveries in biochemistry—the existence of RNA enzymes or ribozymes. The best-characterized ribozymes are the self-splicing group I introns, RNase P, and the hammerhead ribozyme (discussed below). Most of the activities of these ribozymes are based on two fundamental reactions: transesterification (Fig. 26-14) and phosphodiester bond hydrolysis (cleavage). The substrate for a ribozyme is often an RNA molecule, and it may even be part of the ribozyme itself. When its substrate is RNA, the RNA catalyst can make use of base-pairing interactions to align the substrate for the reaction.

Ribozymes Share Features with Protein Enzymes

Like protein enzymes, ribozymes vary greatly in size. A self-splicing group I intron may have more than 400 nucleotides. In comparison, the hammerhead ribozyme consists of two RNA strands with a total of just 41 nucleotides. **P4** Also as with protein enzymes, the three-dimensional structure of ribozymes is important for function. Ribozymes, like protein enzymes, are inactivated by heating above their melting temperature or by the addition of denaturing agents or complementary oligonucleotides, which disrupt normal base-pairing patterns. Ribozymes can also be inactivated if essential nucleotides are changed. The secondary structure of a self-splicing group I intron from the 26S rRNA precursor of *Tetrahymena* is shown in detail in **Figure 26-37**. This secondary structure highlights the large number of base-pairing and other noncovalent interactions that must occur for the ribozyme to adopt a catalytic structure. Just as amino acid mutations can change activities of protein enzymes, nucleotide mutations can alter the noncovalent interactions required for ribozyme folding and catalysis.

P4 Ribozymes share several properties with enzymes besides accelerating the reaction rate, including kinetic behavior and specificity. Binding of the guanosine cofactor to the *Tetrahymena* group I rRNA intron is saturable ($K_m < 30$ μM) and can be competitively inhibited by 3′-deoxyguanosine. The intron is very precise in its excision reaction, largely due to a segment called the **internal guide sequence** that can base-pair with exon sequences near the 5′ splice site (Fig. 26-37). This pairing promotes the alignment of specific bonds to be cleaved and rejoined.

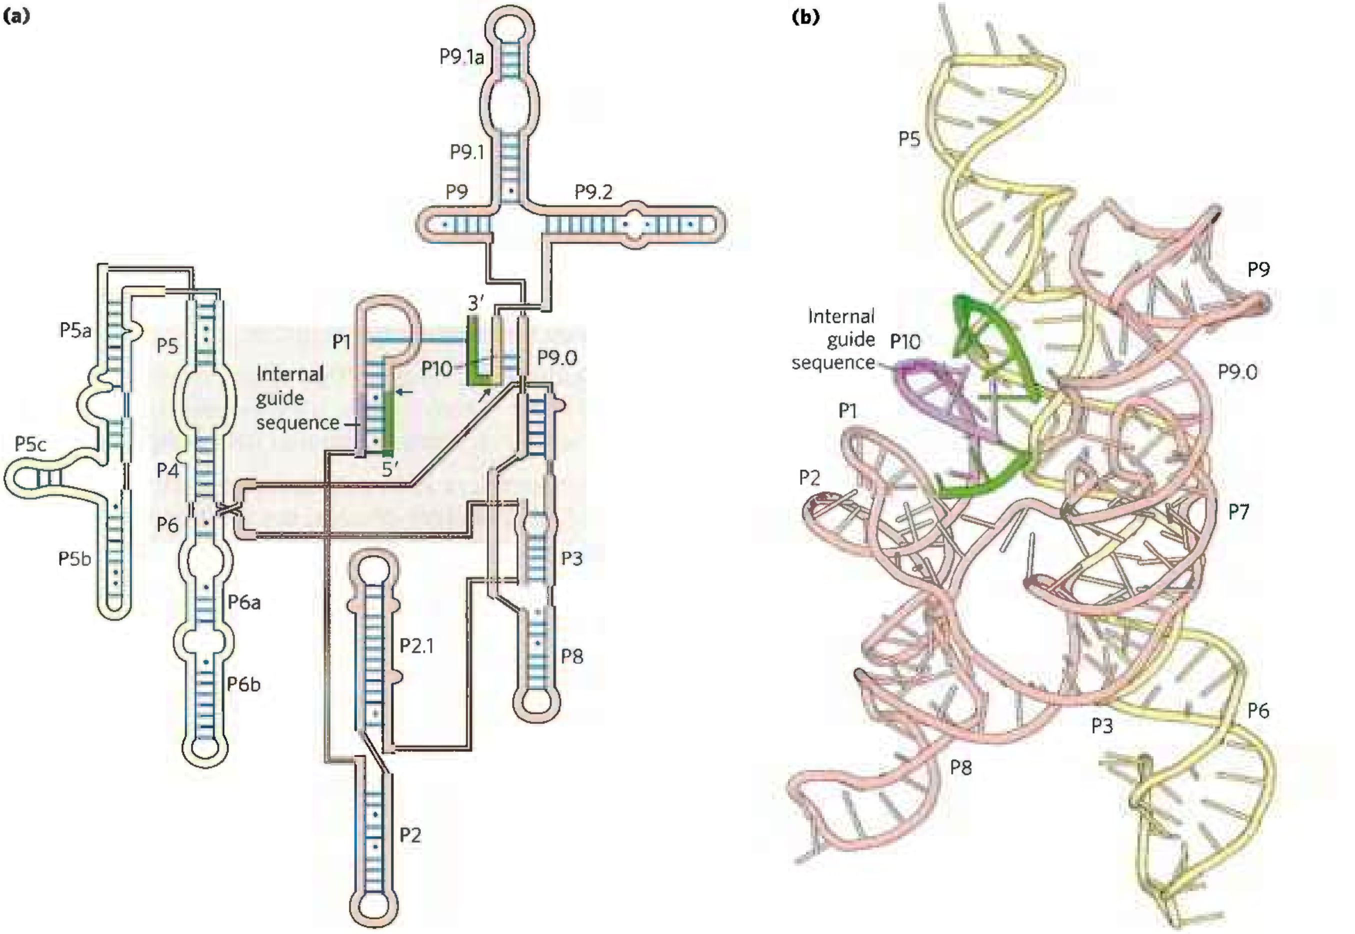

FIGURE 26-37 Secondary structure of the self-splicing rRNA intron of *Tetrahymena*. (a) A two-dimensional representation of secondary structure immediately prior to the initiation of the reaction. Intron sequences are shaded yellow and light red; flanking exon sequences are green; the internal guide sequences that help to align reacting segments at the active site are purple. Each thin, light-red line represents a bond between adjacent nucleotides in a continuous sequence (a device necessitated by showing this complex molecule in two dimensions). Short blue lines represent normal base pairing; blue dots indicate G–U base pairs. All nucleotides are shown. The catalytic core of the self-splicing activity is shaded in gray. Some base-paired regions are labeled (P1, P3, P2.1, P5a, and so forth) according to an established convention for this RNA molecule. The P1 region, which contains the internal guide sequence (purple), is the location of the 5′ splice site (black arrow). Part of the internal guide sequence pairs with the end of the 3′ exon, bringing the 5′ and 3′ splice sites (black arrows) into close proximity. (b) Three-dimensional structure of a reaction intermediate of the same intron, after guanosine-mediated cleavage (Fig. 26-14) and prior to exon ligation. Segments are colored as in (a). [Data from (a) PDB ID 1GID, J. H. Cate et al., *Science* 273:1678, 1996. (b) PDB ID 1U6B, P. L. Adams et al., *Nature* 430:45, 2004.]

Because the intron itself is chemically altered during the splicing reaction—its ends are cleaved—it may seem to lack one key enzymatic property: the ability to catalyze multiple reactions. Closer inspection has shown that after excision, the 414 nucleotide intron from *Tetrahymena* rRNA can, in vitro, act as a true enzyme (but in vivo it is quickly degraded). A series of intramolecular cyclization and cleavage reactions in the excised intron leads to the loss of 19 nucleotides from its 5′ end. The remaining 395 nucleotide, linear RNA—referred to as L-19 IVS (*int*ervening *s*equence)—promotes nucleotidyl transfer reactions in which some oligonucleotides are lengthened at the expense of others (**Fig. 26-38**). The best substrates are oligonucleotides, such as a synthetic $(C)_5$ oligomer, that can base-pair with the same guanylate-rich internal guide sequence that held the 5′ exon in place for self-splicing.

The enzymatic activity of the L-19 IVS ribozyme results from a cycle of transesterification reactions mechanistically similar to self-splicing. Each ribozyme molecule can process about 100 substrate molecules per hour and is not altered in the reaction—that is, the intron acts as a catalyst. It follows Michaelis-Menten kinetics, is specific for RNA oligonucleotide substrates, and can be competitively inhibited. The k_{cat}/K_m (specificity constant) is 10^3 $M^{-1}s^{-1}$, lower than that of many protein enzymes, but the ribozyme accelerates hydrolysis by a factor of 10^{10} relative to the uncatalyzed reaction. **P4** It makes use of substrate orientation, covalent catalysis, and metal-ion catalysis—all strategies shared with protein enzymes.

Ribozymes Participate in a Variety of Biological Processes

E. coli RNase P has both an RNA component (the M1 RNA, with 377 nucleotides) and a protein component (M_r 17,500). In 1983, Sidney Altman and Norman Pace and their coworkers discovered that under some conditions, the M1 RNA alone is capable of catalysis, cleaving tRNA precursors at the correct position. The protein component apparently serves to stabilize the RNA or facilitate its function in vivo. The RNase P ribozyme recognizes the three-dimensional shape of its pre-tRNA substrate, along with the CCA sequence, and thus can cleave the 5′ leaders from diverse tRNAs (Fig. 26-25).

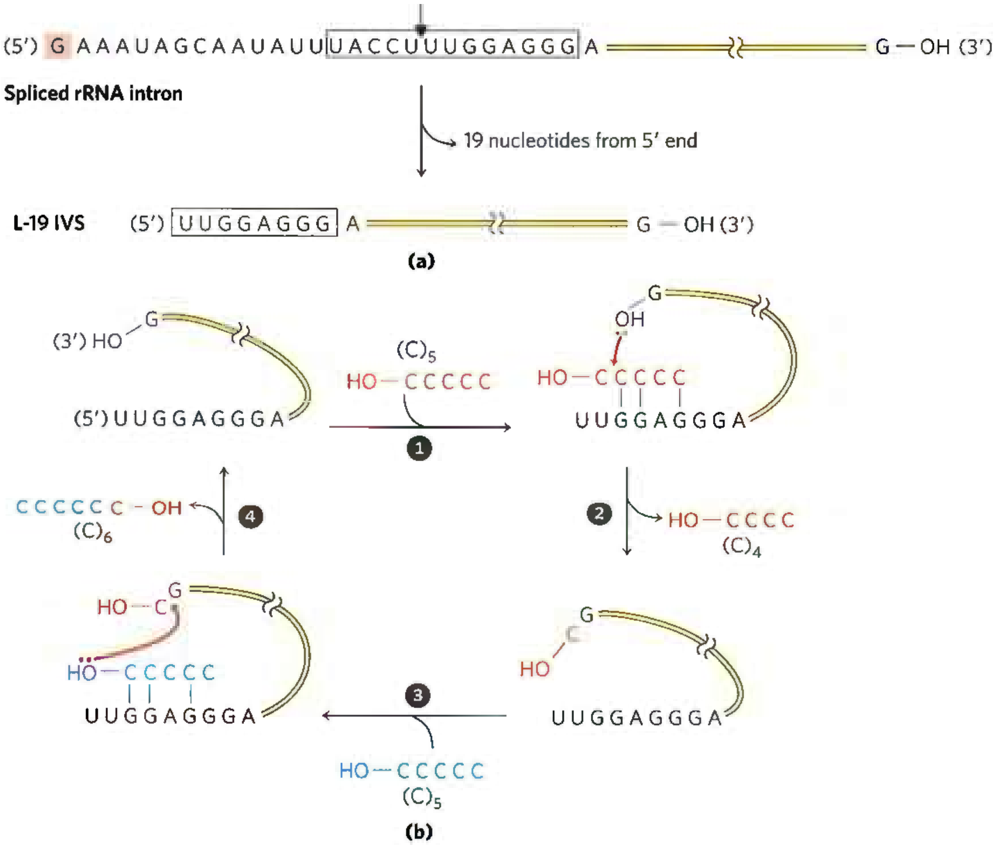

FIGURE 26-38 In vitro catalytic activity of L-19 IVS. (a) L-19 IVS (intervening sequence, the term once used for intron) is generated by the autocatalytic removal of 19 nucleotides from the 5′ end of the spliced *Tetrahymena* intron. The cleavage site is indicated by the arrow in the internal guide sequence (boxed). The G residue (shaded) added in the first step of the splicing reaction is part of the removed sequence. A portion of the internal guide sequence remains at the 5′ end of L-19 IVS. (b) L-19 IVS lengthens some RNA oligonucleotides at the expense of others in a cycle of transesterification reactions (steps ❶ through ❹). The 3′ OH of the G residue at the 3′ end of L-19 IVS plays a key role in this cycle (note that this is *not* the G residue added in the splicing reaction). $(C)_5$ is one of the ribozyme's better substrates because it can base-pair with the guide sequence remaining in the intron.

The known catalytic repertoire of ribozymes continues to expand. Some virusoids, small RNAs associated with plant RNA viruses, include a structure that promotes a self-cleavage reaction; the small hammerhead ribozyme illustrated in **Figure 26-39** is in this class, catalyzing the hydrolysis of an internal phosphodiester bond. There are at least nine structural classes of ribozymes that engage in self-cleavage; all use general acid and base catalysis (Fig. 6-8) to promote the attack of a 2′-hydroxyl group on an adjacent phosphodiester bond. Despite being surrounded by proteins, the splicing reaction that occurs in a spliceosome relies on a catalytic center formed by the U2, U5, and U6 snRNAs and intron (see Figs 26-16 and 26-17). And, as we shall see in Chapter 27, an RNA component of ribosomes catalyzes the synthesis of proteins. Exploring catalytic RNAs has provided new insights into catalytic function in general and has important implications for our understanding of the origin and evolution of life on this planet.

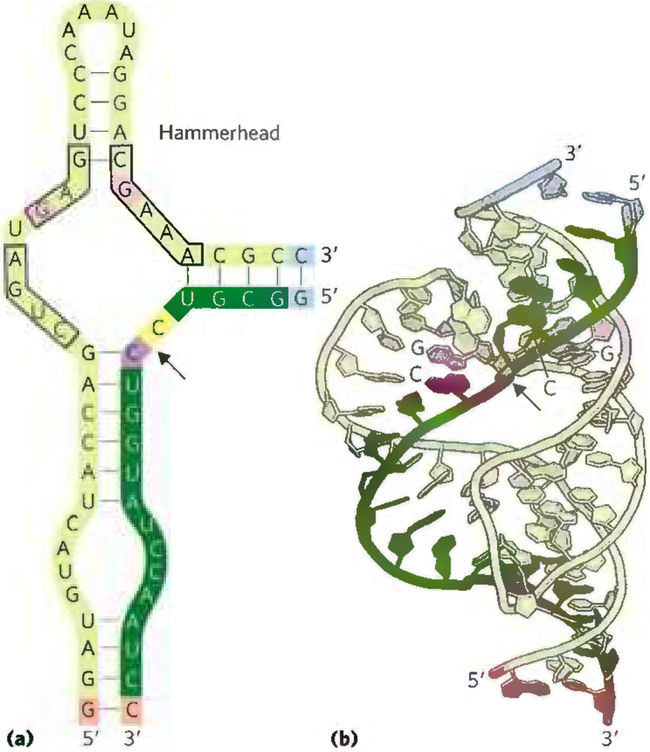

FIGURE 26-39 Hammerhead ribozyme. Some virusoid RNAs include small segments that promote site-specific RNA cleavage reactions associated with replication. These segments are called hammerhead ribozymes, because their secondary structures are shaped like the head of a hammer. (a) The minimal sequences required for catalysis by the ribozyme. The boxed nucleotides are highly conserved and are required for catalytic function. Guanine nucleotides shaded pink form part of the active site. The arrow indicates the site of self-cleavage. (b) Three-dimensional structure of a hammerhead ribozyme (see Fig. 8-25b for a view of another hammerhead ribozyme). The strands are colored as in (a). The hammerhead ribozyme is a metalloenzyme; Mg^{2+} ions are required for activity in vivo. The phosphodiester bond at the site of self-cleavage is indicated by an arrow. [Data from PDB ID 3ZD5, M. Martick and W. G. Scott, *Cell* 126:309, 2006.]

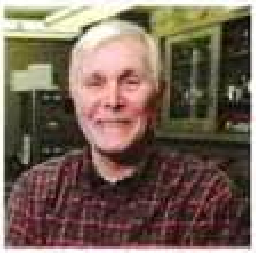
Ribozymes Provide Clues to the Origin of Life in an RNA World

The extraordinary complexity and order that distinguish living from inanimate systems are key manifestations of fundamental life processes. Maintaining the living state requires that *selected* chemical transformations occur very rapidly — especially those that use environmental energy sources and synthesize elaborate or specialized cellular macromolecules. Life depends on powerful and selective catalysts — enzymes — and on informational systems capable of both securely storing the blueprint for these enzymes and accurately reproducing the blueprint for generation after generation. Chromosomes encode the blueprint not for the cell but for the enzymes that construct and maintain the cell. The parallel demands for information and catalysis present a classic conundrum: what came first, the information needed to specify structure or the enzymes needed to maintain and transmit the information?

How might a self-replicating polymer come to be? How might it maintain itself in an environment where the precursors for polymer synthesis are scarce? How could evolution progress from such a polymer to the modern DNA-protein world? These difficult questions can be addressed by careful experimentation, providing clues about how life on Earth began and evolved.



Carl Woese, 1928–2012 [Steve Kagan.]

P4 The unveiling of the structural and functional complexity of RNA led Carl Woese, Francis Crick, and Leslie Orgel to propose in the 1960s that this macromolecule might serve as both information carrier and catalyst. Since that time, at least six lines of evidence have given increasing substance to their **RNA world hypothesis**.

1. Prebiotic Chemistry Experiments The probable origin of purine and pyrimidine bases is suggested by experiments designed to test hypotheses about prebiotic chemistry (pp. 31–32). Beginning with simple molecules thought to be present in the early atmosphere (CH_4, NH_3, H_2O, H_2), electrical discharges mimicking lightning generate, first, more reactive molecules such as HCN and aldehydes, then an array of amino acids and organic acids (see Fig. 1-33). When molecules such as HCN become abundant, purine and pyrimidine bases are synthesized in detectable amounts. Remarkably, a concentrated solution of ammonium cyanide, refluxed for a few days, generates adenine in yields of up to 0.5% (**Fig. 26-40**). Adenine may well have been the first and most abundant nucleotide constituent to appear on Earth. Intriguingly, most enzyme cofactors contain adenosine as part of their structure, although it plays no direct role in the

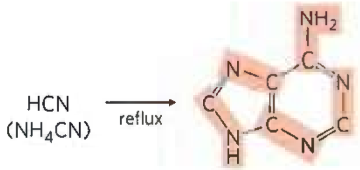


FIGURE 26-40 Experiments supporting prebiotic synthesis of adenine from ammonium cyanide. Adenine is derived from five molecules of cyanide, denoted by shading.

cofactor function (see Fig. 8-41). This may suggest an evolutionary relationship. Based on the simple synthesis of adenine from cyanide, adenine may simply have been abundant and available.

2. The Existence of Catalytic RNAs P4 In an "RNA world," RNAs, not proteins, act as catalysts. Perhaps more than anything else, the discovery of ribozymes gave life to the RNA world hypothesis and led to widespread speculation that an RNA world might have been important in the transition from prebiotic chemistry to life (see Fig. 1-35). The parent of all life on this planet, in the sense that it could reproduce itself across the generations from the origin of life to the present, might have been a self-replicating RNA, or a polymer with equivalent chemical characteristics.

3. The Expanding Catalytic Repertoire of Ribozymes A self-replicating polymer would quickly use up available supplies of precursors provided by the relatively slow processes of prebiotic chemistry. Thus, from an early stage in evolution, metabolic pathways would be required to generate precursors efficiently, with the synthesis of precursors presumably catalyzed by ribozymes. The extant ribozymes found in nature have a limited repertoire of catalytic functions, and of the ribozymes that may once have existed, no trace is left. To explore the RNA world hypothesis more deeply, we need to know whether RNA has the potential to catalyze the many different reactions needed in a primitive system of metabolic pathways.

The search for RNAs with new catalytic functions has been aided by the development of a method that rapidly searches pools of random polymers of RNA and extracts those with particular activities; known as **SELEX**, this is nothing less than accelerated evolution in a test tube (**Box 26-4**). It has been used to generate RNA molecules that bind to amino acids, organic dyes, nucleotides, cyanocobalamin, and other molecules. Researchers have isolated ribozymes that catalyze ester and amide bond formation, S_N2 reactions, metallation of (addition of metal ions to) porphyrins, and carbon–carbon bond formation. The evolution of enzymatic cofactors with nucleotide "handles" that facilitate their binding to ribozymes might have further expanded the repertoire of chemical processes available to primitive metabolic systems.

4. The Structure of the Ribosome As we shall see in Chapter 27, some natural RNA molecules, components of ribosomes, catalyze the formation of peptide bonds, offering a glimpse of how the RNA world might have been transformed by the greater catalytic potential of proteins. The evolution of a capacity to synthesize proteins would have been a major event in the RNA world, allowing the generation of polymers that could greatly stabilize complex RNA structures. However, the onset of peptide synthesis would also have hastened the demise of the RNA world. Proteins simply have more catalytic potential. The information-carrying role of RNA may have passed to DNA because DNA is chemically more stable. RNA replicase and reverse transcriptase may be modern versions of enzymes that once played important roles in making the transition to the modern DNA-based system.

5. Extant Vestiges of an RNA World The known functions of RNA continue to multiply with each decade. Retroviruses, other RNA viruses, and retrotransposons inhabit a semi-independent universe, maintaining a parasitic existence within the biosphere. For evolutionary biologists, these almost-living entities provide a window on key steps in the evolution of life. Transposons may have been an early innovation in an RNA world. With the appearance of the first, inefficient self-replicators, transposition could have been an important alternative to replication as a strategy for successful reproduction and survival. Early parasitic RNAs would simply hop into a self-replicating molecule via catalyzed transesterification, then passively undergo replication. Natural selection would have driven transposition to become site-specific, targeting sequences that did not interfere with the catalytic activities of the host RNA. Replicators and RNA transposons could have existed in a primitive symbiotic relationship, each contributing to the evolution of the other. Modern introns, retroviruses, and transposons may all be vestiges of a "piggyback" strategy pursued by early parasitic RNAs. These elements continue to make major contributions to the evolution of their hosts.

6. Progress in the Search for an RNA Replicator The RNA world hypothesis requires a nucleotide polymer to reproduce itself. Can a ribozyme bring about its own synthesis in a template-directed manner? Researchers are getting closer to finding such a ribozyme or ribozyme system. For example, Gerald Joyce and colleagues, in 2009, reported on the first set of two ribozymes that could cross-catalyze each other's formation (**Fig. 26-41**). One ribozyme, E, catalyzes the joining of two oligonucleotides (A′ and B′) to create a second, complementary

BOX 26-4 METHODS

The SELEX Method for Generating RNA Polymers with New Functions

SELEX (*s*ystematic *e*volution of *l*igands by *ex*ponential enrichment) is used to generate **aptamers**, oligonucleotides selected to tightly bind a specific molecular target. The process is generally automated to allow rapid identification of one or more aptamers with the desired binding specificity.

Figure 1 illustrates how SELEX is used to select an RNA species that binds tightly to ATP. In step ①, a random mixture of RNA polymers is subjected to "unnatural selection" by passing it through a resin to which ATP is attached. The practical limit for the complexity of an RNA mixture is about 10^{15} different sequences, which allows complete randomization of 25 nucleotides ($4^{25} = 10^{15}$). For longer RNAs, the RNA pool used to initiate the search does not include all possible sequences. RNA polymers that pass through the column are discarded (step ②); those that bind to ATP are washed from the column with salt solution and collected (step ③). In step ④, the collected RNA polymers are amplified by reverse transcriptase to make many DNA complements to the selected RNAs, then an RNA polymerase makes many RNA complements of the resulting DNA molecules. Finally, in step ⑤, this new pool of RNA is subjected to the same selection procedure, and the cycle is repeated a dozen or more times. At the end, only a few aptamers—in this case, RNA sequences with considerable affinity for ATP—remain.

Critical sequence features of an RNA aptamer that binds ATP are shown in Figure 2; molecules with this general structure bind ATP (and other adenosine nucleotides) with $K_d < 50\ \mu\text{M}$. Figure 3 presents the three-dimensional structure of a 36 nucleotide RNA aptamer (shown as a complex with AMP) generated by SELEX. This RNA has the backbone structure shown in Figure 2.

In addition to its use in exploring the potential functionality of RNA, SELEX has an important practical side in identifying short RNAs with pharmaceutical uses. Finding an aptamer that binds specifically to every potential therapeutic target may be impossible, but the capacity of SELEX to rapidly select and amplify a specific oligonucleotide sequence from a highly complex pool of sequences makes this a promising approach for generating new therapies. For example, one could select an RNA that binds tightly to a receptor protein prominent in the plasma membrane of cells in a particular cancerous tumor. Blocking the activity of the receptor, or targeting a toxin to the tumor cells by attaching it to the aptamer, would kill the cells. SELEX also has been used to select DNA aptamers that detect anthrax spores. Many other promising applications are under development. ■

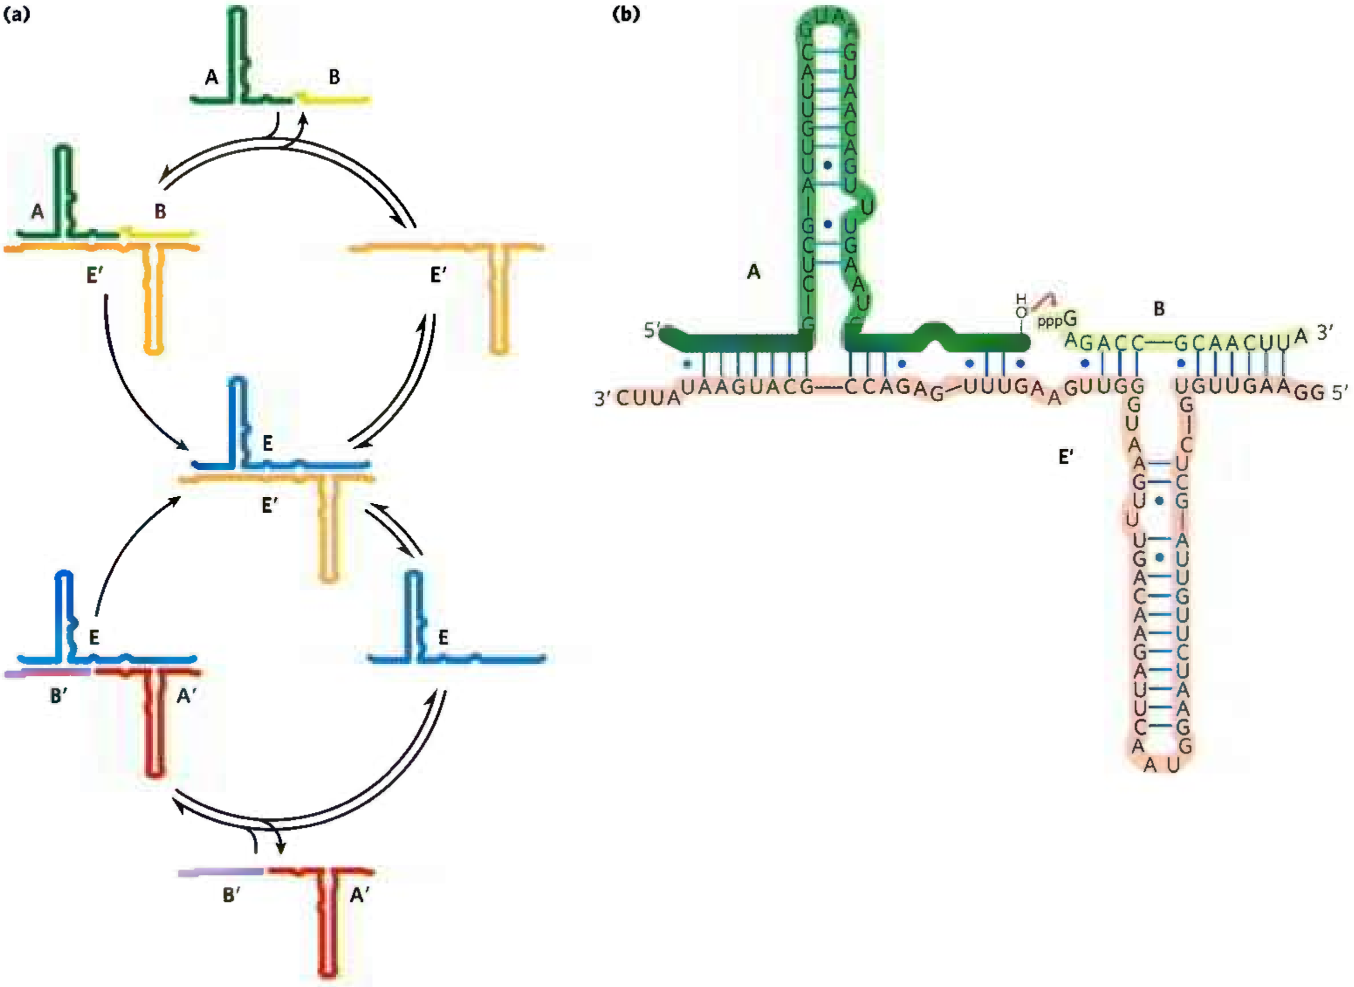

FIGURE 26-41 Self-sustained replication of an RNA enzyme. This system has many of the properties of a living system. The RNA molecules incorporate information and catalytic function, and the reactions produce an exponential increase in the product RNAs. When variants of the RNA substrates are introduced, the system undergoes natural selection such that the best replicators eventually dominate the population. (a) A possible reaction scheme. Oligoribonucleotides A and B anneal to ribozyme E′ and are ligated catalytically to form ribozyme E. The joining of oligoribonucleotides A′ and B′ is similarly catalyzed by ribozyme E. The levels of E and E′ grow exponentially, with a doubling time of about one hour at 42 °C, as long as there is a supply of the precursors A, B, A′, and B′. (b) The ligation reaction involves attack of the 3′ OH of one oligoribonucleotide on the α phosphate of the 5′-triphosphate of the other oligoribonucleotide. Pyrophosphate is released. Base pairing of the substrates with the ribozyme plays a key role in aligning the substrates for the reaction. [Information from T. A. Lincoln and G. F. Joyce, *Science* 323:1229, 2009.]

ribozyme called E′. E′ could then catalyze the joining of two other oligonucleotides (A and B) to form another molecule of E. In this system, the formation of E and E′ was templated, and the amounts grew exponentially as long as substrates were available and proteins were absent. The system evolved so that more-efficient enzymes appeared in the population. A more general RNA-polymerase-like ribozyme was described in 2011 by Philipp Holliger and colleagues.

Although the RNA world remains a hypothesis, with many gaps yet to be explained, experimental evidence supports a growing list of its key elements. Further experimentation should increase our understanding. Important clues to the puzzle will be found in the workings of fundamental chemistry, in living cells, and perhaps on other planets.

SUMMARY 26.4 *Catalytic RNA and the RNA World Hypothesis*

- Ribozymes and protein-based enzymes share common features, including folded three-dimensional structures, inactivation by denaturation, acceleration of reaction rates, saturable kinetics, and reaction specificity.
- Ribozymes and RNA-based catalysts are present in organisms today and are involved in a wide range of activities, including tRNA processing, nuclear pre-mRNA splicing, and translation.
- The evolution of life on Earth may have included an RNA world in which RNA was the central information carrier and catalyst before proteins and DNA emerged as key players. The existence of ribozymes provides a powerful piece of evidence in support of this hypothesis.

KEY TERMS

Terms in bold are defined in the glossary.

ribonucleoprotein (RNP)	960
transcription	960
messenger RNA (mRNA)	960
transfer RNA (tRNA)	960
ribosomal RNA (rRNA)	960
noncoding RNA (ncRNA)	960
transcriptome	960
DNA-dependent RNA polymerase	961
template strand	962
nontemplate strand	962
coding strand	962
promoter	963
consensus sequence	963

PROBLEMS

1. RNA Polymerase (a) How long would it take for the *E. coli* RNA polymerase to synthesize the primary transcript for the *E. coli* genes encoding the enzymes for lactose metabolism, the 5,300 bp *lac* operon? **(b)** How far along the DNA would the transcription "bubble" formed by RNA polymerase move in 10 seconds? **(c)** Assuming that human Pol II transcribes at a similar rate, how long does it take to transcribe the 2,000,000 bp dystrophin gene?

2. Error Correction by RNA Polymerases DNA polymerases are capable of editing and error correction, whereas the capacity for error correction in RNA polymerases seems to be limited. Given that a single base error in either replication or transcription can lead to an error in protein synthesis, suggest a possible biological explanation for this difference.

3. RNA Posttranscriptional Processing Predict the likely effects of a mutation in the sequence (5′)AAUAAA in a eukaryotic mRNA transcript.

4. Coding versus Template Strands The RNA genome of phage Qβ is the nontemplate strand, or coding strand, and when introduced into the cell, it functions as an mRNA. Suppose the RNA replicase of phage Qβ synthesized primarily template-strand RNA and uniquely incorporated this, rather than nontemplate strands, into the viral particles. What would be the fate of the template strands when they entered a new cell? What enzyme would have to be included in the viral particles for successful invasion of a host cell?

5. Transcription The gene encoding the *E. coli* enzyme enolase begins with the sequence ATGTCCAAAATCGTA. What is the sequence of the RNA transcript specified by this part of the gene?

6. The Chemistry of Nucleic Acid Biosynthesis Describe three properties common to the reactions catalyzed by DNA polymerase, RNA polymerase, reverse transcriptase, and RNA replicase. How is the enzyme polynucleotide phosphorylase similar to and different from these four enzymes?

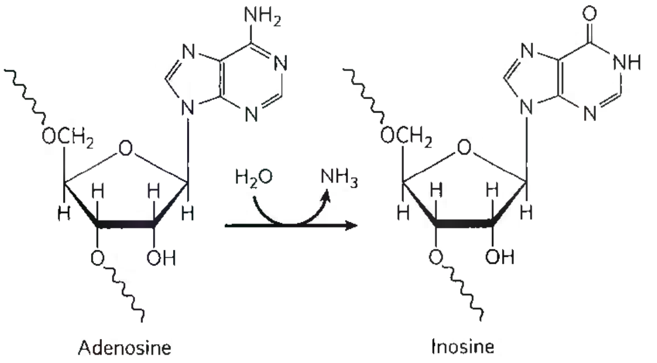
7. RNA Processing I While studying human transcription in the 1960s, James Darnell carried out an experiment that has become a classic in biochemistry, but at the time, it was incredibly perplexing. Darnell and coworkers used radioactive isotopes, such as $[^{32}\text{P}]$-labeled phosphate, to isolate and quantify RNAs from a cultured line of human cancer cells (HeLa). With this approach, they were able to identify those RNAs present in the nucleus and those present in the cytoplasm. The results were puzzling, because it was obvious that a large amount of transcription was occurring in the nucleus, but comparatively little radioactive mRNA was isolated from the cytoplasm. Moreover, the nuclear-isolated RNAs were much longer than those isolated from the cytoplasm. What can account for these observations?

8. The Transcriptome If a cell's genome is completely known, is it possible to determine the cell's transcriptome—the sequence of all the RNAs being produced by the cell—without additional information? Explain.

9. RNA Splicing What is the minimum number of transesterification reactions needed to splice an intron from a pre-mRNA transcript? Explain.

10. RNA Processing II Blocking the splicing of a particular pre-mRNA in a vertebrate cell also blocks a nucleotide modification reaction occurring in the rRNA. Suggest a reason for this.

11. RNA Modification I Researchers Brenda Bass and Harold Weintraub discovered double-stranded RNA-specific adenosine deaminases (ADARs) in 1987. These enzymes recognize double-stranded regions of mRNA and convert adenosine bases to inosine within these regions.



(a) When ADAR encounters a double-stranded RNA substrate in water that also contains $H_2[^{18}O]$, radioactive oxygen incorporates into the RNA. Draw a reaction mechanism for ADAR that accounts for this observation.
(b) After ADAR reacts with a double-stranded RNA, the RNA duplex sometimes spontaneously unwinds to form single strands. Why might this occur?
(c) What is a possible consequence of adenosine to inosine conversion in the coding sequence of an mRNA?

12. Organization of RNA Processing In eukaryotes, pre-mRNA splicing by the spliceosome occurs only in the nucleus and translation of mRNAs occurs only in the cytosol. Why might the separation of these two activities into different cellular compartments be important?

13. RNA Modification II In addition to rRNAs and tRNAs, many human mRNAs also contain modified nucleotides, in particular N^6-methyladenosine.
(a) How might incorporation of N^6-methyladenosine impact RNA processing?
(b) Incorporation of N^6-methyladenosine into the 3′ untranslated region (UTR; see Fig. 9-24) of the MAT2A transcript, which encodes a methionine adenosyltransferase, regulates the metabolism of the cofactor *S*-adenosylmethionine. Why would metabolism of *S*-adenosylmethionine be linked to N^6-methyladenosine formation?

14. RNA Genomes RNA viruses have relatively small genomes. For example, the single-stranded RNAs of retroviruses have about 10,000 nucleotides, and the Qβ RNA is only 4,220 nucleotides long. How might the properties of reverse transcriptase and RNA replicase have contributed to the small size of these viral genomes?

15. Screening of RNAs by SELEX The practical limit for the number of different RNA sequences that can be screened in a SELEX experiment is 10^{15}. **(a)** Suppose you are working with oligonucleotides that are 36 nucleotides long. How many sequences exist in a randomized pool containing every sequence possible? **(b)** What percentage of these can a SELEX experiment screen? **(c)** Suppose you wish to select an RNA molecule that catalyzes the hydrolysis of a particular ester. From what you know about catalysis, propose a SELEX strategy that might allow you to select the appropriate catalyst.

16. Slow Death The death cap mushroom, *Amanita phalloides*, contains several dangerous substances, including the lethal α-amanitin. This toxin blocks RNA elongation in consumers of the mushroom by binding to eukaryotic RNA polymerase II with very high affinity; it is deadly in concentrations as low as 10^{-8} M. The initial reaction to ingestion of the mushroom is gastrointestinal distress (caused by some of the other toxins). These symptoms disappear, but about 48 hours later, the mushroom-eater dies, usually from liver dysfunction. Speculate on why it takes this long for α-amanitin to kill.

17. Detection of Rifampin-Resistant Strains of Tuberculosis Rifampin is an important antibiotic used to treat tuberculosis and other mycobacterial diseases. Some strains of *Mycobacterium tuberculosis*, the causative agent of tuberculosis, are resistant to rifampin. These strains become resistant through mutations that alter the *rpoB* gene, which encodes the β subunit of the RNA polymerase (see Fig. 26-10). Rifampin cannot bind to the mutant RNA polymerase and so is unable to block the initiation of transcription. DNA sequences from a large number of rifampin-resistant *M. tuberculosis* strains have been found to have mutations in a specific 69 bp region of *rpoB*. One well-characterized rifampin-resistant strain has a single base pair alteration in *rpoB* that results in a His residue being replaced by an Asp residue in the β subunit.
(a) Based on your knowledge of protein chemistry, what technique could you use to detect whether a particular strain produces the rpoB His → Asp mutant protein?
(b) Based on your knowledge of nucleic acid chemistry, what technique could you also use to identify the mutant forms of *rpoB*?

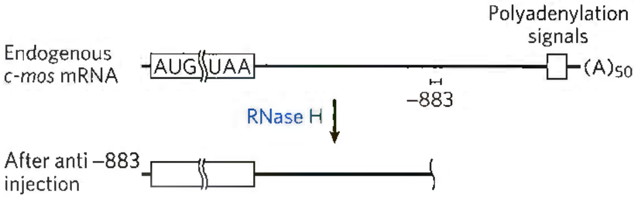
BIOCHEMISTRY ONLINE

18. The Ribonuclease Gene Human pancreatic ribonuclease has 128 amino acid residues.
(a) What is the minimum number of nucleotide pairs required to code for this protein?
(b) The mRNA expressed in human pancreatic cells was copied with reverse transcriptase to create a "library" of human DNA. The sequence of the mRNA coding for human pancreatic ribonuclease was determined by sequencing the complementary DNA (cDNA) from this library that included an open reading frame for the protein. Use the nucleotide database at NCBI (www.ncbi.nlm.nih.gov/nucleotide) to find the published sequence of this mRNA. (Search for accession number D26129.) What is the length of this mRNA?
(c) How can you account for the discrepancy between the size you calculated in (a) and the actual length of the mRNA?

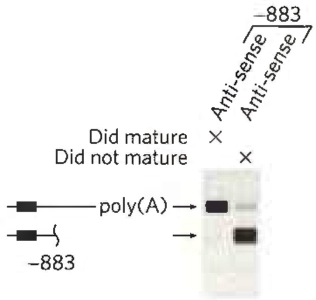
DATA ANALYSIS PROBLEM

19. Amputated RNAs with Prosthetic Tails The Wickens lab studies the dramatic effects of RNA processing on how a cell utilizes mRNAs, such as the c-*mos* (cellular *mo*use *s*arcoma) protooncogene, which controls meiosis and embryonic cell cycles in vertebrates. In frogs (*Xenopus*), expression of the c-*mos* protein is essential for maturation of oocytes after exposure to progesterone and embryo formation.

Specific RNAs can be cleaved (amputated) in *Xenopus* oocytes by injection of antisense DNA oligonucleotides that will hybridize to the mRNA. The formation of an RNA/DNA duplex triggers cleavage of the RNA strand by cellular RNase H. The figure below depicts the results of amputation of the c-*mos* mRNA after oligo injection. In this case, the oligonucleotide targeted the −883 region of the c-*mos* mRNA. This region is downstream of the c-*mos* open reading frame (depicted by the AUG start and UAA stop codons) within the 3′ untranslated region (3′UTR).



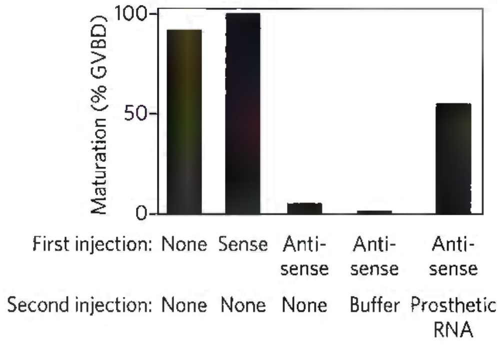
After injection of a sense oligonucleotide, the oocyte maturation percentage was nearly unchanged. However, when an antisense oligonucleotide was injected, the maturation percentage was reduced by ~60%. The c-*mos* mRNA was isolated from oocytes that either did or did not mature after injection of the antisense oligonucleotide. The mRNAs were analyzed by gel electrophoresis followed by northern blotting, as shown below. In a northern blot, RNAs are separated by gel electrophoresis according to their size, transferred to a membrane, and then detected by hybridization to radioactive or fluorescent complementary DNA probes.



(a) What can you conclude about the importance of the c-*mos* mRNA poly(A) tail on oocyte maturation?

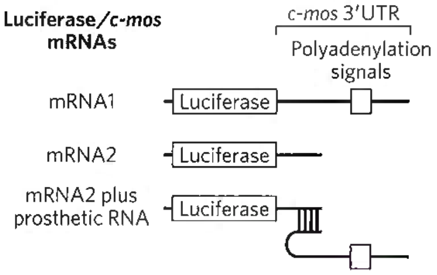
(b) Why was a sense oligonucleotide used in some experiments?

Members of the Wickens lab then decided to inject a prosthetic RNA after amputation of the c-*mos* mRNA. The prosthetic RNA contained the c-*mos* mRNA 3′UTR as well as a region complementary to the amputated c-*mos* mRNA. Their observations are shown below. In these experiments, oocyte maturation was measured by the percentage of cells in which germinal vesicle breakdown (% GVBD) was observed. GVBD occurs when the oocyte nucleus (called the germinal vesicle) dissolves and the cell resumes meiosis.



(c) How do you explain these results?

Wickens lab scientists then tried attaching the c-*mos* mRNA 3′UTR to an unrelated reporter enzyme. In this case, they used luciferase, whose enzymatic activity can easily be measured by luminescence (see Box 13-2). The total luciferase activity is also proportional to the amount of luciferase protein being produced by the cell. They tried attaching the entire c-*mos* mRNA 3′UTR (mRNA1), the amputated 3′UTR (mRNA2), or a combination of the amputated 3′UTR with the prosthetic poly(A) tail to luciferase. High luciferase activity was observed only when either the entire c-*mos* mRNA 3′UTR was used or when the prosthetic poly(A) tail was included along with the amputated 3′UTR.



(d) What does this experiment tell you about the likely function of the 3′UTR and poly(A) tail for the c-*mos* mRNA and in oocyte maturation?

(e) How might these results be useful for controlling cellular gene expression?

PROTEIN METABOLISM

27.1 The Genetic Code *1006*
27.2 Protein Synthesis *1015*
27.3 Protein Targeting and Degradation *1041*

Almost every biological process requires one or more proteins. A typical cell requires thousands of different proteins at any given moment. These proteins must be synthesized in response to the cell's current needs, modified to alter their activity or fate, transported (targeted) to their appropriate cellular locations, and degraded when no longer needed. Dozens of separate processes contribute to cellular **proteostasis**, the steady-state complement of proteins that enable the life of a cell at any given moment.

Many of the fundamental components and mechanisms used by the protein biosynthetic machinery are remarkably well conserved in all life-forms, from bacteria to higher eukaryotes, indicating that they were present in the last universal common ancestor (LUCA) of all extant organisms. Whereas the chapter focuses on protein biosynthesis, all aspects of proteostasis are considered. The principles that guide our approach are interrelated, reflecting all of these realities and more.

P1 **Information is expensive.** This principle, noted in earlier chapters, is particularly well illustrated by protein synthesis. Protein synthesis consumes more cellular resources than any other process in most cells. The 15,000 ribosomes, 100,000 molecules of protein synthesis–related protein factors and enzymes, and 200,000 tRNA molecules in a typical bacterial cell can account for more than 35% of the cell's dry weight. Overall, almost 300 *different* macromolecules cooperate to synthesize polypeptides. Protein synthesis can account for up to 90% of the chemical energy used by a cell for all biosynthetic reactions. Why? The enzymatic synthesis of an amide bond should require little energetic input. However, the sequence of amino acids in a protein is a form of biological information. Synthesis of each amide (peptide) bond between two *particular* amino acids is ensured by the investment of more than four nucleoside triphosphates (NTPs).

P2 **The genetic code is nearly universal and arose early in evolution.** This is one of the many characteristics of living systems that ties all of them to a common ancestor. Even the rare exceptions to code universality reinforce this rule.

P3 **The genetic code functions via linker molecules.** The tRNAs are the crucial adaptor, matching amino acids with DNA codons.

P4 **Proteins are synthesized by RNAs.** The study of protein synthesis offers another important reward: a look at a world of RNA catalysts that may have existed in an RNA world before the dawn of life "as we know it." Proteins are synthesized by a gigantic RNA enzyme.

P5 **Protein metabolism is regulated at many levels.** The resource investment in protein synthesis ensures that many layers of regulation work together to determine which proteins are synthesized at any given moment. However, proteins often function only in particular cellular locations and at particular times. Mechanisms for spatial and temporal regulation—protein targeting, activation, and eventual degradation—exhibit complexities that can approach those of the biosynthetic processes.

Several major advances set the stage for our present knowledge of protein biosynthesis (**Fig. 27-1**). First, in the early 1950s, Paul Zamecnik and Elizabeth Keller discovered the ribonucleoprotein particles in which protein synthesis occurs. These particles, visible in animal tissues by electron microscopy, were later named ribosomes. Soon after, Francis Crick considered how the genetic information encoded in the 4-letter language of nucleic acids could be translated into the 20-letter language of proteins. In 1955, Crick postulated that a small nucleic acid could serve the role of an adaptor, with one part of the adaptor molecule binding a specific

FIGURE 27-2 Crick's adaptor hypothesis. Francis Crick proposed that one end of a small nucleotide adaptor could bind a specific amino acid and the other end could recognize a nucleotide sequence in the mRNA. Today we know that the amino acid is covalently bound at the 3′ end of a tRNA molecule and that a specific nucleotide triplet elsewhere in the tRNA interacts with a particular triplet codon in mRNA through hydrogen bonding of complementary bases.

amino acid and another part recognizing the nucleotide sequence encoding that amino acid in an mRNA (**Fig. 27-2**). Crick's adaptor hypothesis was soon verified when Mahlon Hoagland and Zamecnik discovered tRNA. The structure of alanyl-tRNA was reported by Robert Holley in 1964. The tRNA adaptor "translates" the nucleotide sequence of an mRNA into the amino acid sequence of a polypeptide. The overall process of mRNA-guided protein synthesis is often referred to simply as **translation**. Hoagland, Zamecnik, and Elizabeth Keller also discovered that amino acids were "activated" for protein synthesis when incubated with ATP and the cytosolic fraction of liver cells. The amino acids became attached to a heat-stable soluble RNA—the tRNA—to form **aminoacyl-tRNAs**. The enzymes that catalyze this process are the **aminoacyl-tRNA synthetases**.

These developments soon led to recognition of the major stages of protein synthesis and ultimately to elucidation of the genetic code that specifies each amino acid. In subsequent decades, ribosomes were purified and their protein and rRNA components were dissected. Elucidation of the three-dimensional structures of ribosomes was completed by 2000, confirming a hypothesis first put forward by Harry Noller two decades earlier: it is the rRNA, rather than ribosomal proteins, that catalyzes peptide bond formation.

27.1 The Genetic Code

By the 1960s, it was apparent that at least three nucleotide residues of DNA are necessary to encode each amino acid. The four code letters of DNA (A, T, G, and C) in groups of two can yield only $4^2 = 16$ different combinations, insufficient to encode 20 amino acids. Groups of three, however, yield $4^3 = 64$ different combinations. Deciphering the genetic code quickly became a major goal.

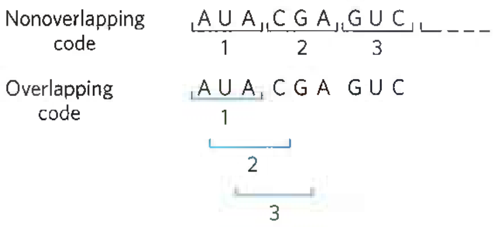

FIGURE 27-3 Overlapping versus nonoverlapping genetic codes. In a nonoverlapping code, codons (numbered consecutively) do not share nucleotides. In an overlapping code, some nucleotides in the mRNA are shared by different codons. In a triplet code with maximum overlap, many nucleotides, such as the third nucleotide from the left (A), are shared by three codons. A nonoverlapping code provides much more flexibility in the triplet sequence of neighboring codons and therefore in the possible amino acid sequences designated by the code.

FIGURE 27-4 The triplet, nonoverlapping code. Evidence for the general nature of the genetic code came from many types of experiments, including genetic experiments on the effects of deletion and insertion mutations. Inserting or deleting one base pair (shown here in the mRNA transcript) alters the sequence of all amino acids coded by the mRNA following the change. Combining insertion and deletion mutations affects some amino acids but can eventually restore the correct amino acid sequence. Adding or subtracting three nucleotides (not shown) leaves the remaining triplets intact, providing evidence that a codon has three, rather than four or five, nucleotides. The triplet codons shaded in gray are those transcribed from the original gene; codons shaded in blue are new codons resulting from the insertion or deletion mutations.

The Genetic Code Was Cracked Using Artificial mRNA Templates

Several key properties of the genetic code were established in early genetic studies. A **codon** is a triplet of nucleotides that codes for a specific amino acid. In all living systems, translation occurs in such a way that these nucleotide triplets are read in a successive, nonoverlapping fashion (Figs. 27-3, 27-4). A specific first codon in the sequence establishes the **reading frame**, in which a new codon begins every three nucleotide residues. There is no punctuation between codons for successive amino acid residues. The amino acid sequence of a protein is defined by a linear sequence of contiguous triplets. In principle, any given single-stranded DNA or mRNA sequence has three possible reading frames. Each reading frame gives a different sequence of codons (Fig. 27-5), but only one is likely to encode a given protein. A key question remained: what were the three-letter code words for each amino acid?

In 1961, Marshall Nirenberg and J. Heinrich Matthaei reported the first breakthrough. They incubated synthetic polyuridylate, poly(U), with an *Escherichia coli* extract, GTP, ATP, and a mixture of the 20 amino acids in 20 different tubes, each tube containing a different radioactively labeled amino acid. Because poly(U) mRNA is made up of many successive UUU triplets, it should promote the synthesis of a polypeptide containing only the amino acid encoded by UUU. A radioactive polypeptide was formed only in the tube containing radioactive phenylalanine. Nirenberg and Matthaei therefore concluded that the triplet codon UUU encodes phenylalanine. The same approach soon revealed that polycytidylate, poly(C), encodes a polypeptide containing only proline (polyproline), and that polyadenylate, poly(A), encodes polylysine. Polyguanylate did not generate any polypeptide in this experiment because it spontaneously forms tetraplexes (see Fig. 8-20d) that cannot be bound by ribosomes.

The synthetic polynucleotides used in such experiments were prepared by using polynucleotide phosphorylase (p. 987), which catalyzes the formation of RNA polymers starting from ADP, UDP, CDP, and GDP. This enzyme, discovered by physician/biochemist Severo Ochoa, requires no template and makes polymers with a base composition that directly reflects the relative concentrations of the nucleoside 5′-diphosphate precursors in the medium. If polynucleotide phosphorylase is presented with only UDP, it makes only poly(U). If it is presented with a mixture of five parts ADP and one part CDP, it makes a polymer in which about five-sixths of the residues are adenylate and one-sixth is cytidylate. This random polymer is likely to have many triplets of the sequence AAA; smaller numbers of AAC, ACA, and CAA triplets; relatively few ACC, CCA, and CAC triplets; and very few CCC triplets (Table 27-1). Using a variety of artificial mRNAs made by polynucleotide phosphorylase

TABLE 27-1 Incorporation of Amino Acids into Polypeptides in Response to Random Polymers of RNA

Amino acid	Observed frequency of incorporation (Lys = 100)	Tentative assignment for nucleotide composition of corresponding codon[a]	Expected frequency of incorporation based on assignment (Lys = 100)
Asparagine	24	A_2C	20
Glutamine	24	A_2C	20
Histidine	6	AC_2	4
Lysine	100	AAA	100
Proline	7	AC_2, CCC	4.8
Threonine	26	A_2C, AC_2	24

Note: Presented here is a summary of data from one of the early experiments designed to elucidate the genetic code. A synthetic RNA containing only A and C residues in 5:1 ratio directed polypeptide synthesis, and both the identity and the quantity of incorporated amino acids were determined. Based on the relative abundance of A and C residues in the synthetic RNA, and assigning the codon AAA (the most likely codon) a frequency of 100, there should be three different codons of composition A_2C, each at a relative frequency of 20; three of composition AC_2, each at a relative frequency of 4.0; and CCC at a relative frequency of 0.8. The CCC assignment was based on information derived from prior studies with poly(C). Where two tentative codon assignments are made, both are proposed to code for the same amino acid.

[a] These designations of nucleotide composition contain no information on nucleotide sequence (except, of course, AAA and CCC).

TABLE 27-2 Trinucleotides That Induce Specific Binding of Aminoacyl-tRNAs to Ribosomes

Trinucleotide	Relative increase in ^{14}C-labeled aminoacyl-tRNA bound to ribosome[a] Phe-tRNA^{Phe}	 Lys-tRNA^{Lys}	 Pro-tRNA^{Pro}
UUU	4.6	0	0
AAA	0	7.7	0
CCC	0	0	3.1

Information from M. Nirenberg and P. Leder, *Science* 145:1399, 1964.

[a] Each number represents the factor by which the amount of bound ^{14}C increased when the indicated trinucleotide was present, relative to a control with no trinucleotide.

from different starting mixtures of ADP, GDP, UDP, and CDP, the Nirenberg and Ochoa groups soon identified the base compositions of the triplets coding for almost all the amino acids. Although these experiments revealed the base composition of the coding triplets, they usually could not reveal the sequence of the bases.

KEY CONVENTION Much of the following discussion deals with tRNAs. The amino acid specified by a tRNA is indicated by a superscript, such as tRNA^{Ala}, and the aminoacylated tRNA is designated by a hyphenated name, such as alanyl-tRNA^{Ala} or Ala-tRNA^{Ala}. ■

In 1964, Nirenberg and Philip Leder achieved another experimental breakthrough. Isolated *E. coli* ribosomes would bind a specific aminoacyl-tRNA in the presence of the corresponding synthetic polynucleotide messenger. For example, ribosomes incubated with poly(U) and phenylalanyl-tRNA^{Phe} (Phe-tRNA^{Phe}) bind both RNAs, but if the ribosomes are incubated with poly(U) and some other aminoacyl-tRNA, the aminoacyl-tRNA is not bound, because it does not recognize the UUU triplets in poly(U) (**Table 27-2**). Even trinucleotides could promote specific binding of appropriate tRNAs, so these experiments could be carried out with chemically synthesized small oligonucleotides. With this technique, researchers determined which aminoacyl-tRNA bound to 54 of the 64 possible triplet codons. For some codons, either no aminoacyl-tRNA or more than one would bind. Another method was needed to complete and confirm the entire genetic code.

At about this time, a complementary approach was provided by H. Gobind Khorana, who developed chemical methods to synthesize polyribonucleotides with defined, repeating sequences of two to four bases. The polypeptides produced by these mRNAs had one or a few amino acids in repeating patterns. These patterns, when combined with information from the random polymers used by Nirenberg and colleagues, permitted unambiguous codon assignments. The copolymer $(AC)_n$, for example, has alternating ACA and CAC codons: ACACACACACACACA. The polypeptide synthesized on this messenger contained equal amounts of threonine and histidine. Given that a histidine codon has one A and two Cs (Table 27-1), CAC must code for histidine and ACA for threonine.

Consolidation of the results from many experiments permitted assignment of 61 of the 64 possible codons. The other three were identified as termination codons, in part because they disrupted amino acid coding patterns when they occurred in a synthetic RNA polymer (**Fig. 27-6**). Meanings for all the triplet codons (tabulated in **Fig. 27-7**) were established by 1966 and have been verified in many different ways. The cracking of the genetic code is regarded as one of the most important scientific discoveries of the twentieth century.

P2 Codons are the key to the translation of genetic information, directing the synthesis of specific proteins. The reading frame is set when translation of an mRNA molecule begins, and it is maintained as the synthetic machinery reads sequentially from one triplet to the next. If the initial

FIGURE 27-7 "Dictionary" of amino acid code words in mRNAs. The codons are written in the 5′→3′ direction. The third base of each codon (in bold type) plays a lesser role in specifying an amino acid than the first two. The three termination codons are shaded in light red, the initiation codon AUG in green. All the amino acids except methionine and tryptophan have more than one codon. In most cases, codons that specify the same amino acid differ only at the third base.

reading frame is off by one or two bases, or if translation somehow skips a nucleotide in the mRNA, all the subsequent codons will be out of register; the result is usually a "missense" protein with a garbled amino acid sequence.

Several codons serve special functions (Fig. 27-7). The **initiation codon** AUG is the most common signal for the beginning of a polypeptide in all cells, in addition to coding for Met residues in internal positions of polypeptides. The **termination codons** (UAA, UAG, and UGA), also called stop codons or nonsense codons, normally signal the end of polypeptide synthesis and do not code for any known amino acids.

As described in Section 27.2, initiation of protein synthesis in the cell is an elaborate process that relies on initiation codons and other signals in the mRNA. **P1** In retrospect, the experiments of Nirenberg, Khorana, and others to identify codon function should not have worked in the absence of initiation codons. Serendipitously, experimental conditions caused the normally complex initiation requirements for protein synthesis (unknown at the time) to be relaxed. Diligence combined with chance to produce a breakthrough—a common occurrence in the history of biochemistry.

In a random sequence of nucleotides, 1 in every 20 codons in each reading frame is, on average, a termination codon. In general, a reading frame without a termination codon among 50 or more consecutive codons is referred to as an **open reading frame (ORF)**. Long ORFs usually correspond to genes that encode proteins. In the analysis of sequence databases, sophisticated programs are used to search for ORFs in order to find genes among the often-huge background of nongenic DNA. An uninterrupted gene coding for a typical protein with a molecular weight of 60,000 would require an ORF with 500 or more codons.

A striking feature of the genetic code is that an amino acid may be specified by more than one codon, so the code is described as **degenerate**. This does *not* suggest that the code is flawed: although an amino acid may have two or more codons, each codon specifies only one amino acid. The degeneracy of the code is not uniform. Whereas methionine and tryptophan have single codons, for example, three amino acids (Arg, Leu, Ser) have six codons, five amino acids have four, isoleucine has three, and nine amino acids have two (**Table 27-3**).

The genetic code is nearly universal. With the intriguing exception of a few minor variations in mitochondria, some bacteria, and some single-celled eukaryotes, amino acid codons are identical in all species examined so far. Human beings, *E. coli*, tobacco plants, amphibians, and viruses share the same genetic code. This suggests that all life-forms have a common evolutionary ancestor, whose genetic code has been preserved throughout biological evolution. Even the variations (**Box 27-1**) reinforce this theme.

TABLE 27-3 Degeneracy of the Genetic Code

Amino acid	Number of codons	Amino acid	Number of codons
Met	1	Tyr	2
Trp	1	Ile	3
Asn	2	Ala	4
Asp	2	Gly	4
Cys	2	Pro	4
Gln	2	Thr	4
Glu	2	Val	4
His	2	Arg	6
Lys	2	Leu	6
Phe	2	Ser	6

BOX 27-1

Exceptions That Prove the Rule: Natural Variations in the Genetic Code

In biochemistry, as in other disciplines, exceptions to general rules can be problematic for instructors and frustrating for students. At the same time, though, they teach us that life is complex and they inspire us to search for more surprises. Understanding the exceptions can even reinforce the original rule in unpredictable ways.

One would expect little room for variation in the genetic code. Even a single amino acid substitution can have profoundly deleterious effects on the structure of a protein. Nevertheless, variations in the code do occur in some organisms, and they are both interesting and instructive. The types of variation and their rarity provide powerful evidence for a common evolutionary origin of all living things.

To alter the code, changes must occur in the gene(s) encoding one or more tRNAs, with the obvious target for alteration being the anticodon. Such a change would lead to the systematic insertion of an amino acid at a codon that, according to the standard code (see Fig. 27-7), does not specify that amino acid. The genetic code, in effect, is defined by two elements: (1) the anticodons on tRNAs, which determine where an amino acid is placed in a growing polypeptide, and (2) the specificity of the enzymes — the aminoacyl-tRNA synthetases — that charge the tRNAs, which determines the identity of the amino acid attached to a given tRNA.

Most sudden changes in the code would have catastrophic effects on cellular proteins, so code alterations are more likely to persist where relatively few proteins would be affected — such as in small genomes encoding only a few proteins. The biological consequences of a code change could also be limited by restricting changes to the three termination codons, which do not generally occur *within* genes. This pattern is, in fact, observed.

Of the very few variations in the genetic code that we know of, most occur in mitochondrial DNA (mtDNA), which encodes only 10 to 20 proteins. Mitochondria have their own tRNAs, so their code variations do not affect the much larger cellular genome. The most common changes in mitochondria involve termination codons. These changes affect termination in the products of only a subset of genes, and sometimes the effects are minor, because the genes have multiple (redundant) termination codons.

Vertebrate mtDNAs have genes that encode 13 proteins, 2 rRNAs, and 22 tRNAs (see Fig. 19-40). Given the small number of codon reassignments, along with an unusual set of wobble rules (p. 1012), the 22 tRNAs are sufficient to decode the protein-coding genes, as opposed to the 32 tRNAs required for the standard code. In mitochondria, these changes can be viewed as a kind of genomic streamlining, as a smaller genome confers a replication advantage on the organelle. Four codon families (in which the amino acid is determined entirely by the first two nucleotides) are decoded by a single tRNA with a U residue in the first (or wobble) position in the anticodon. Either the U pairs somehow with any of the four possible bases in the third position of the codon or a "two out of three" mechanism is used — that is, no base pairing is needed at the third position. Other tRNAs recognize codons with either A or G in the third position, and yet others recognize U or C, so that virtually all the tRNAs recognize either two or four codons.

In the standard code, only two amino acids are specified by single codons: methionine and tryptophan (see Table 27-3). If all mitochondrial tRNAs recognize two codons, we would expect additional Met and Trp codons in mitochondria. And we find that the single most common code variation is UGA, usually a termination codon, specifying tryptophan. The tRNA^{Trp} recognizes and inserts a Trp residue at either UGA or the usual Trp codon, UGG. The second most common variation is conversion of AUA from an Ile codon to a Met codon; the usual Met codon is AUG, and a single tRNA recognizes both codons. The known coding variations in mitochondria are summarized in Table 1.

Turning to the much rarer changes in the codes for cellular (as distinct from mitochondrial) genomes, we find that the only known variation in a bacterium is again the use of UGA to encode Trp residues, occurring in the simplest free-living cell, *Mycoplasma capricolum*. Among eukaryotes, rare extramitochondrial coding changes occur in a few species of ciliated protists, in which both termination codons UAA and UAG can specify glutamine. There are also rare but interesting cases in which stop codons have been adapted to encode amino acids that are not among the standard 20, as detailed in Box 27-2.

Changes in the code need not be absolute; a codon might not always encode the same amino acid. For example, in many bacteria — including *E. coli* — GUG (Val) is sometimes used as an initiation codon that specifies Met. This occurs only for those genes in which the GUG is properly located relative to particular mRNA sequences that affect the initiation of translation (as discussed in Section 27.2).

Wobble Allows Some tRNAs to Recognize More than One Codon

When several different codons specify one amino acid, the difference between them usually lies at the third base position (at the 3′ end). For example, alanine is encoded by the triplets GCU, GCC, GCA, and GCG. The codons for most amino acids can be symbolized by XY$^{A}_{G}$ or XY$^{U}_{C}$. The first two letters of each codon are the primary determinants of specificity, a feature that has some interesting consequences.

P3 Transfer RNAs base-pair with mRNA codons at a three-base sequence on the tRNA called the **anticodon**.

TABLE 1 **Known Variant Codon Assignments in Mitochondria**

	Codons[a]				
	UGA	AUA	AGA AGG	CUN	CGG
Normal (cellular) code assignment	Stop	Ile	Arg	Leu	Arg
Animals					
Vertebrates	Trp	Met	Stop	+	+
Drosophila	Trp	Met	Ser	+	+
Yeasts					
Saccharomyces cerevisiae	Trp	Met	+	Thr	+
Torulopsis glabrata	Trp	Met	+	Thr	?
Schizosaccharomyces pombe	Trp	+	+	+	+
Filamentous fungi	Trp	+	+	+	+
Trypanosomes	Trp	+	+	+	+
Higher plants	+	+	+	+	Trp
Chlamydomonas reinhardtii	?	+	+	+	?

[a] N indicates any nucleotide; + indicates that a codon has the same meaning as in the cellular code; ? indicates that a codon was not observed in this mitochondrial genome.

The most surprising alteration in the genetic code occurs in some fungal species of the genus *Candida*, as originally discovered for *Candida albicans*. *C. albicans* is an organism of high genomic complexity, yet its genetic code has undergone a dramatic change: the CUG codon, which usually encodes Leu residues, encodes Ser instead. The natural selection pressure for this change is completely unknown. Furthermore, Ser and Leu are quite different in chemical structure. However, even this change can be understood based on the properties of a universal code. When several codons encode the same amino acid and use multiple tRNAs, not all of the codons are used with equal frequency. In a phenomenon called **codon bias**, some codons for a particular amino acid are used more frequently (sometimes much more frequently) than others. The tRNAs for the frequently used codons are often present at much higher concentrations than the tRNAs required for the rarely used codons. Code degeneracy leads to the presence of six codons for Leu. In bacteria, CUG often encodes Leu. However, in fungi of genera that are very closely related to *Candida* but do not have the coding change, CUG only rarely encodes Leu and is often entirely absent in highly expressed proteins. A change in the coding sense of CUG would thus have a much smaller effect on fungal cell metabolism than might be expected if all codons were used equally. The coding change may have occurred by a gradual loss of CUG codons in genes and of the tRNA that recognizes CUG as a Leu codon, followed by a capture event — a mutation in the anticodon of a tRNA^{Ser} that allowed it to recognize CUG. Alternatively, there may have been an intermediate stage in which CUG was recognized as encoding both Leu and Ser, perhaps with contextual signals in the mRNAs that helped one tRNA or another recognize specific CUG codons (see Box 27-2). Phylogenetic analysis indicates that the reassignment of CUG as a Ser codon occurred in *Candida* ancestors about 150 million to 170 million years ago.

These variations tell us that the code is not quite as universal as once believed, but that its flexibility is severely constrained. The variations are obviously derivatives of the cellular code, and no example of a completely different code has been found. The limited scope of code variants strengthens the principle that all life on this planet evolved on the basis of a single (slightly flexible) genetic code.

The first base of the codon in mRNA (read in the 5′→3′ direction) pairs with the third base of the anticodon (**Fig. 27-8a**). If the anticodon triplet of a tRNA recognized only one codon triplet through Watson-Crick base pairing at all three positions, cells would have a different tRNA for each amino acid codon. This is not the case, however, because the anticodons in some tRNAs include the nucleotide inosinate (designated I), which contains the uncommon base hypoxanthine (see Fig. 8-5b). Inosinate can form hydrogen bonds with three different nucleotides — A, U, and C (Fig. 27-8b) — although these pairings are much weaker than the hydrogen bonds of Watson-Crick base pairs G≡C and A=U. In yeast, one tRNA^{Arg} has the anticodon (5′)ICG, which recognizes three arginine codons: (5′)CGA, (5′)CGU, and (5′)CGC. The first two bases are identical (CG) and form strong Watson-Crick base pairs with the corresponding bases of the anticodon, but the third base (A, U, or C) forms rather weak hydrogen bonds with the I residue at the first position of the anticodon.

Examination of these and other codon-anticodon pairings led Crick to conclude that the third base of most codons pairs rather loosely with the corresponding base of its anticodon; to use his picturesque word, the third base of such codons (and the first base of their corresponding anticodons) "wobbles." Crick proposed a set of four relationships called the **wobble hypothesis**:

1. The first two bases of an mRNA codon always form strong Watson-Crick base pairs with the corresponding bases of the tRNA anticodon and confer most of the coding specificity.
2. The first base of the anticodon (reading in the 5′→3′ direction; this pairs with the third base of the codon) determines the number of codons recognized by the tRNA. When the first base of the anticodon is C or A, base pairing is specific and only one codon is recognized by that tRNA. When the first base is U or G, binding is less specific and two different codons may be read. When inosine (I) is the first (wobble) nucleotide of an anticodon, three different codons can be recognized—the maximum number for any tRNA. These relationships are summarized in **Table 27-4**.
3. When an amino acid is specified by several different codons, the codons that differ in either of the first two bases require different tRNAs.
4. A minimum of 32 tRNAs are required to translate all 61 codons (31 to encode the amino acids, 1 for initiation).

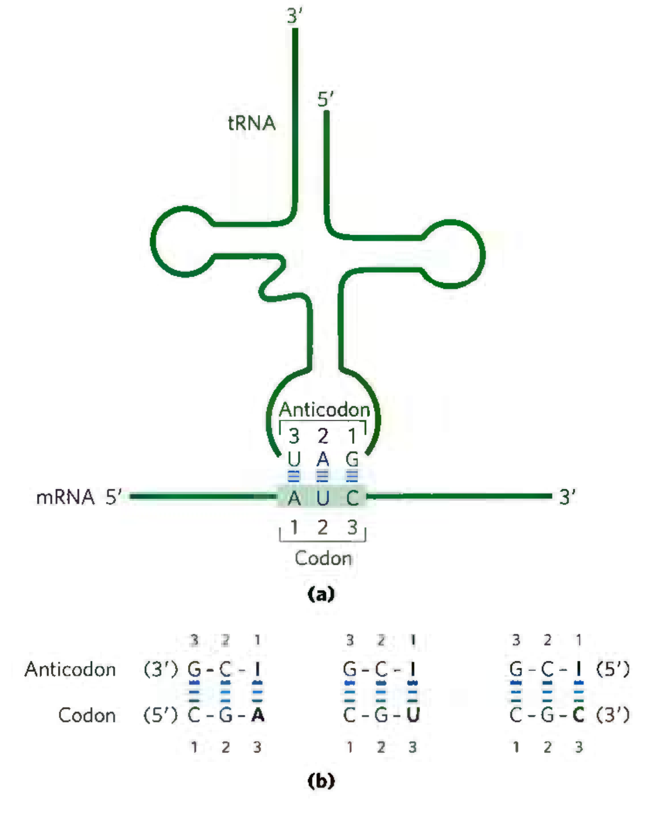

FIGURE 27-8 Pairing relationship of codon and anticodon. (a) Alignment of the two RNAs is antiparallel. The tRNA is shown in the traditional cloverleaf configuration. (b) Three different codon pairing relationships are possible when the tRNA anticodon contains inosinate.

The wobble (or third) base of the codon contributes to specificity, but because it pairs only loosely with its corresponding base in the anticodon, it permits rapid dissociation of the tRNA from its codon during protein synthesis. If all three bases of a codon engaged in strong Watson-Crick pairing with the three bases of the anticodon, tRNAs would dissociate too slowly and this would limit the rate of protein synthesis. Codon-anticodon interactions balance the requirements for accuracy and speed.

P3 Although only 32 tRNAs are required to translate all codons, most cells have more than that. The bacterium *E. coli* has 47 different tRNA genes. Many of these are present in multiple copies, such that there are 86 total tRNA genes in the *E. coli* genome.

The Genetic Code Is Mutation-Resistant

The genetic code plays an interesting role in safeguarding the genomic integrity of every living organism. Evolution did not produce a code in which codon assignments appeared at random. Instead, the code is strikingly resistant to the deleterious effects of the most common kinds

TABLE 27-4 How the Wobble Base of the Anticodon Determines the Number of Codons a tRNA Can Recognize

1. One codon recognized:			
	Anticodon	(3′) X—Y—**C** (5′)	(3′) X—Y—**A** (5′)
	Codon	(5′) X′—Y′—**G** (3′)	(5′) X′—Y′—**U** (3′)
2. Two codons recognized:			
	Anticodon	(3′) X—Y—**U** (5′)	(3′) X—Y—**G** (5′)
	Codon	(5′) X′—Y′—$\substack{A\\G}$ (3′)	(5′) X′—Y′—$\substack{C\\U}$ (3′)
3. Three codons recognized:			
	Anticodon	(3′) X—Y—**I** (5′)	
	Codon	(5′) X′—Y′—$\substack{A\\U\\C}$ (3′)	

Note: X and Y denote bases complementary to and capable of strong Watson-Crick base pairing with X′ and Y′, respectively. Wobble bases—in the 3′ position of codons and 5′ position of anticodons—are shaded.

of mutations—**missense mutations**, in which a single new base pair replaces another. In the third, or wobble, position of the codon, single base substitutions produce a change in the encoded amino acid only about 25% of the time. Most such changes are thus **silent mutations**, in which the nucleotide is different but the encoded amino acid remains the same.

Due to the types of spontaneous DNA damage that affect genomes (see Chapter 8), the most frequent missense mutation is a **transition mutation**, in which a purine is replaced by a purine, or a pyrimidine by a pyrimidine (for example, G≡C changed to A=T). All three codon positions have evolved so that there is some resistance to transition mutations. A mutation in the first position of the codon will usually produce an amino acid coding change, but the change often results in an amino acid with similar chemical properties. This is especially true for the hydrophobic amino acids that dominate the first column of the code shown in Figure 27-7. Consider the Val codon GUU. A change to AUU would substitute Ile for Val. A change to CUU would replace Val with Leu. The resulting changes in the structure and/or function of the protein encoded by that gene would often (but not always) be small.

P2 Computational studies have shown that alternative genetic codes, delineated at random, are almost always less resistant to mutation than the existing code. The results indicate that the code underwent considerable streamlining before the appearance of LUCA, the ancestral cell.

The genetic code tells us how protein sequence information is stored in nucleic acids and provides some clues about how that information is translated into protein.

Translational Frameshifting Affects How the Code Is Read

Once the reading frame has been set during protein synthesis, codons are translated without overlap or punctuation until the ribosomal complex encounters a termination codon. The other two possible reading frames usually contain no useful genetic information. Overlap between two genes would necessarily constrain the possible amino acid sequences encoded by one or both genes in the overlap region. However, to make maximal use of limited (and expensive) genetic information, a few genes are structured so that ribosomes "hiccup" at a certain point in the translation of their mRNAs, changing the reading frame from that point on. This allows two or more related but distinct proteins to be produced from a single transcript.

One of the best-documented examples of **translational frameshifting** occurs during translation of the mRNA for the overlapping *gag* and *pol* genes of the Rous sarcoma virus, a retrovirus (see Fig. 26-31). The reading frame for *pol* is offset to the left by one base pair (−1 reading frame) relative to the reading frame for *gag* (**Fig. 27-9**).

The product of the retroviral *pol* gene (reverse transcriptase) is translated as a larger polyprotein, on the same mRNA that is used for the Gag protein alone (see Fig. 26-30). The polyprotein, or Gag-Pol protein, is then trimmed to the mature reverse transcriptase by proteolytic digestion. Production of the polyprotein requires a translational frameshift in the overlap region to allow the ribosome to bypass the UAG termination codon at the end of the *gag* gene (shaded light red in Fig. 27-9).

Frameshifts occur during about 5% of translations of this mRNA, and the Gag-Pol polyprotein (and ultimately reverse transcriptase) is synthesized at about one-twentieth the frequency of the Gag protein, a level that suffices for efficient reproduction of the virus. A similar mechanism produces both the τ and γ subunits of *E. coli* DNA polymerase III from a single *dnaX* gene transcript (see footnote to Table 25-2).

Some mRNAs Are Edited before Translation

RNA editing can involve the addition, deletion, or alteration of nucleotides in the RNA in a manner that affects the meaning of the transcript when it is translated. Addition or deletion of nucleotides has been most commonly observed in RNAs originating from the mitochondrial and chloroplast genomes. The initial transcripts of the genes that encode cytochrome oxidase subunit II in some protist mitochondria provide an example of editing by insertion. These transcripts do not correspond precisely to the sequence needed at the carboxyl terminus of the protein product. A posttranscriptional editing process inserts four U residues that shift the translational reading frame of the transcript. The insertions require a special class of **guide RNAs (gRNAs**; **Fig. 27-10**) that act as templates for the editing process. The added U residues are all located in a small part of the transcript. Note that the base pairing between the initial transcript and the guide RNA includes several G=U base pairs (blue dots), which are common in RNA molecules.

(b) A special class of guide RNAs, complementary to the edited product, acts as templates for the editing process. Note the presence of three G=U base pairs, signified by blue dots to indicate non-Watson-Crick pairing.

RNA editing by alteration of nucleotides most commonly involves the enzymatic deamination of adenosine or cytidine residues, forming inosine or uridine, respectively (**Fig. 27-11**), although other base changes have been described. Inosine is interpreted as a G residue during translation. The adenosine deamination reactions are carried out by *a*denosine *d*eaminases that *a*ct on *R*NA **(ADARs)**. The cytidine deaminations are carried out by the *apoB* mRNA *e*diting *c*atalytic peptide **(APOBEC)** family of enzymes, which includes the *a*ctivation-*i*nduced *d*eaminase **(AID)** enzymes. Both the ADAR and APOBEC groups of deaminase enzymes have a homologous zinc-coordinating catalytic domain.

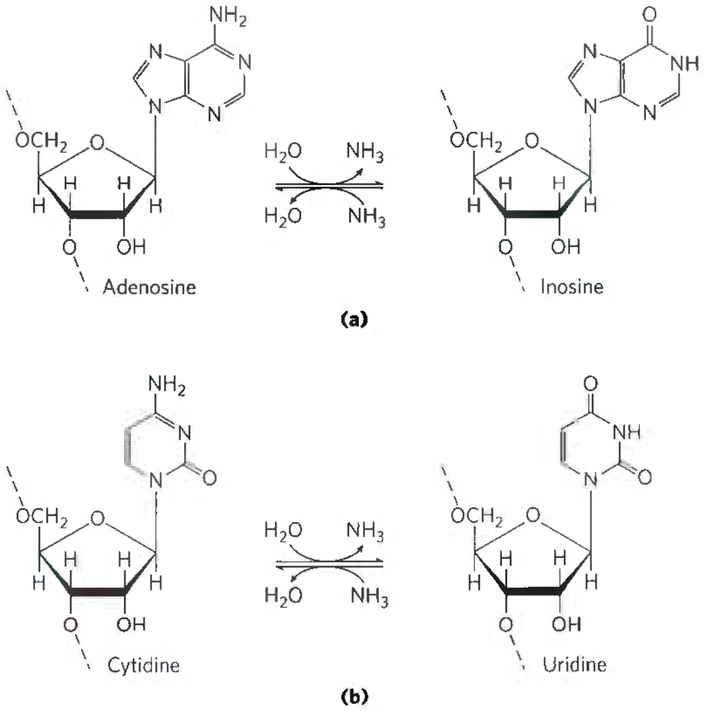

FIGURE 27-11 Deamination reactions that result in RNA editing. (a) Conversion of adenosine nucleotides to inosine nucleotides is catalyzed by ADAR enzymes. (b) Cytidine-to-uridine conversions are catalyzed by the APOBEC family of enzymes.

The ADAR-promoted A-to-I editing of RNA transcripts is particularly common in primates. Most of the editing occurs in Alu elements, a subset of short interspersed elements (SINEs), eukaryotic transposons that are particularly common in primate genomes. Human DNA contains more than a million 300 bp Alu elements, making up about 10% of the genome. These elements are concentrated near protein-coding genes, often in introns and untranslated regions at the 3′ and 5′ ends of transcripts. When it is first synthesized (before processing), the *average* human mRNA includes 10 to 20 Alu elements. Certain microRNAs are also targeted by ADARs. The microRNA (miRNA) alterations generally reduce expression and/or function.

The ADAR enzymes bind to and promote A-to-I editing only in duplex regions of RNA. The abundant Alu elements offer many opportunities for intramolecular base pairing within the transcripts, providing the duplex targets required by ADARs. Some of the editing affects the coding sequences of genes. Defects in ADAR function have been associated with a variety of human neurological conditions, including amyotrophic lateral sclerosis (ALS), epilepsy, and major depression.

There are six general classes of APOBEC cytidine deaminases: APOBEC1–APOBEC5 and AID. The AID proteins function in increasing antibody diversity during immunoglobulin gene maturation (see Figs. 25-42 and 25-43). APOBEC1 and some of the APOBEC3 proteins (seven APOBEC paralogs are encoded by the human genome) edit mRNAs. A well-studied example of RNA editing by APOBEC1-mediated deamination occurs in the gene for the apolipoprotein B component of low-density lipoprotein in vertebrates. One form of apolipoprotein B, apoB-100 (M_r 513,000), is synthesized in the liver; a second form, apoB-48 (M_r 250,000), is synthesized in the intestine. Both are encoded by an mRNA produced from the gene for apoB-100. An APOBEC cytidine deaminase found only in the intestine binds to the mRNA at the codon for amino acid residue 2,153 (CAA=Gln) and converts the C to a U to create the termination codon UAA. The apoB-48 produced in the intestine from this modified

mRNA is simply an abbreviated form (corresponding to the amino-terminal half) of apoB-100 (**Fig. 27-12**). **P1** This reaction permits tissue-specific synthesis of two different proteins from one gene.

APOBEC2, 4, and 5 act on DNA rather than RNA, and their functions are poorly understood. However, their ability to cause genomic mutations can make them a liability to the cell. One or more APOBEC enzymes are often overexpressed in tumor cells, and their mutagenic ability can contribute to the formation of tumors. They also provide a mechanism for introducing multiple mutations into a targeted segment of a chromosome, leading to selective and more rapid evolution of that DNA region.

SUMMARY 27.1 *The Genetic Code*

- The particular amino acid sequence of a protein is constructed through the translation of information encoded in mRNA. This process is carried out by ribosomes. Amino acids are specified by mRNA codons consisting of nucleotide triplets. Translation requires adaptor molecules, the tRNAs, that recognize codons and insert amino acids into their appropriate sequential positions in the polypeptide.
- The base sequences of the codons were deduced from experiments using synthetic mRNAs of known composition and sequence. The codon AUG signals initiation of translation. The triplets UAA, UAG, and UGA are signals for termination. The genetic code is degenerate: it has multiple codons for almost every amino acid. The standard genetic code is universal in all species, with some minor deviations in mitochondria and a few single-celled organisms. The deviations occur in a pattern that reinforces the concept of a universal code.
- The third position in each codon is much less specific than the first and second positions and is said to wobble. This property allows certain tRNAs to recognize more than one codon.
- The genetic code is resistant to the effects of missense mutations. The code evolved so that many nucleotide changes in a DNA codon do not alter the encoded amino acid, or they result in a very conservative alteration.
- Translational frameshifting and RNA editing affect how the genetic code is read during translation.
- RNA editing by ADARs (adenosine deaminases) and APOBECs (cytidine deaminases) also alters the coding sequence of some mRNAs. Many APOBEC enzymes target DNA, where they function in facilitating antibody diversity and suppression of retroviruses and retrotransposons.

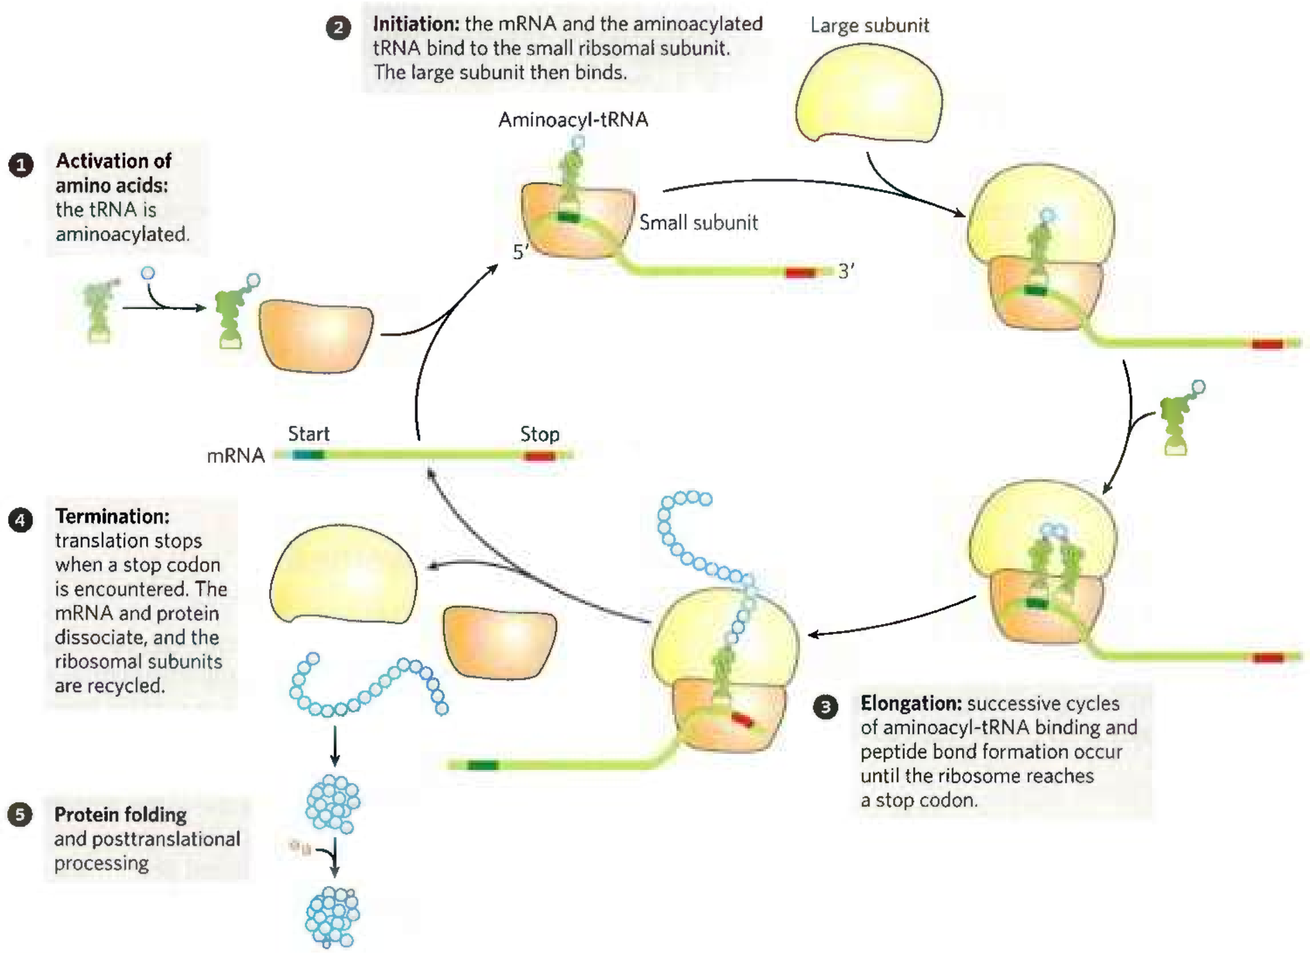
27.2 Protein Synthesis

As we have seen for DNA and RNA (Chapters 25 and 26), the synthesis of polymeric biomolecules can be considered in terms of initiation, elongation, and termination stages. These fundamental processes are typically bracketed by two additional stages: activation of precursors before synthesis and postsynthetic processing of the completed polymer. Protein synthesis follows the same pattern. The activation of amino acids before their incorporation into polypeptides and the posttranslational processing of the completed polypeptide play particularly important roles in ensuring both the fidelity of synthesis and the proper function of the protein product. The process is outlined in **Figure 27-13**. **P1** The cellular components involved in the five stages of protein synthesis in *E. coli* and other bacteria are listed in **Table 27-5**; the requirements in eukaryotic cells are similar, although the components are usually more numerous. Before looking at these five stages in detail, we must examine two key components of protein biosynthesis: the ribosome and tRNAs.

The Ribosome Is a Complex Supramolecular Machine

P1 Each *E. coli* cell contains 15,000 or more ribosomes, which comprise nearly a quarter of the dry weight of the cell. Bacterial ribosomes contain about 65% rRNA and 35% protein; they have a diameter of about 18 nm and are composed of two unequal subunits with sedimentation coefficients of 30S and 50S and a combined sedimentation coefficient of 70S. Both subunits contain dozens of ribosomal proteins (r-proteins) and at least one large rRNA (**Table 27-6**).

As it became clear that ribosomes are the complexes responsible for protein synthesis, and following elucidation of the genetic code, the study of ribosomes accelerated. In the late 1960s Masayasu Nomura and colleagues demonstrated that both ribosomal subunits can be broken down into their RNA and protein components, then reconstituted in vitro. Ribosomal subunits are identified by their S (Svedberg unit) values, sedimentation coefficients that refer to their rate of sedimentation in a centrifuge.



② Initiation: the mRNA and the aminoacylated tRNA bind to the small ribosomal subunit. The large subunit then binds.

④ Termination: translation stops when a stop codon is encountered. The mRNA and protein dissociate, and the ribosomal subunits are recycled.
③ Elongation: successive cycles of aminoacyl-tRNA binding and peptide bond formation occur until the ribosome reaches a stop codon.
⑤ Protein folding and posttranslational processing

FIGURE 27-13 An overview of the five stages of protein synthesis.

TABLE 27-5 Components Required for the Five Major Stages of Protein Synthesis in *E. coli*

Stage	Essential components	
1. Activation of amino acids	20 amino acids 20 aminoacyl-tRNA synthases 32 or more tRNAs	ATP Mg^{2+}
2. Initiation	mRNA *N*-Formylmethionyl-$tRNA^{fMet}$ Initiation codon in mRNA (AUG) 30S ribosomal subunit	50S ribosomal subunit Initiation factors (IF1, IF2, IF3) GTP Mg^{2+}
3. Elongation	Functional 70S ribosomes (initiation complex) Aminoacyl-tRNAs specified by codons	Elongation factors (EF-Tu, EF-Ts, EF-G) GTP Mg^{2+}
4. Termination and ribosome recycling	Termination codon in mRNA Release factors (RF1, RF2, RF3, RRF)	EF-G IF3
5. Folding and posttranslational processing	Chaperones and folding enzymes (PPI, PDI); specific enzymes, cofactors, and other components for removal of initiating residues and signal sequences, additional proteolytic processing, modification of terminal residues, and attachment of acetyl, phosphoryl, methyl, carboxyl, carbohydrate, or prosthetic groups	

Under appropriate experimental conditions, the RNA and protein spontaneously reassemble to form 30S or 50S subunits nearly identical in structure and activity to native subunits. This breakthrough fueled decades of research into the function and structure of ribosomal RNAs and proteins. At the same time, increasingly sophisticated structural methods revealed more and more details about ribosome structure.

TABLE 27-6 **RNA and Protein Components of the *E. coli* Ribosome**

Subunit	Number of different proteins	Total number of proteins	Protein designations	Number and type of rRNAs
30S	21	21	S1–S21	1 (16S rRNA)
50S	33	36	L1–L36[a]	2 (5S and 23S rRNAs)

[a] The L1 to L36 protein designations do not correspond to 36 different proteins. The protein originally designated L7 is a modified form of L12, and L8 is a complex of three other proteins. Also, L26 proved to be the same protein as S20 (and not part of the 50S subunit). This gives 33 different proteins in the large subunit. There are four copies of the L7/L12 protein, with the three extra copies bringing the total protein count to 36.

The dawn of a new millennium illuminated the first high-resolution structures of bacterial ribosomal subunits by Venkatraman Ramakrishnan, Thomas Steitz, Ada Yonath, Harry Noller, and others. This work yielded a wealth of surprises (**Fig. 27-14a**). First, a traditional focus on the protein components of ribosomes was shifted. The ribosomal subunits are huge RNA molecules. In the 50S subunit, the 5S and 23S rRNAs form the structural core. The proteins are secondary elements in the complex, decorating the surface. Second, and most important, there is no protein within 18 Å of the active site for peptide bond formation. **P4** The high-resolution structure thus confirms what Noller had predicted much earlier: the ribosome is a ribozyme. In addition to the insight that the detailed structures of the ribosome and its subunits provide into the mechanism of protein synthesis (as elaborated below), these findings have stimulated a new look at the evolution of life (Section 26.4). The ribosomes of eukaryotic cells have also yielded to structural analysis (Fig. 27-14b).

The bacterial ribosome is complex, with a combined molecular weight of ~2.7 million. The two irregularly shaped ribosomal subunits fit together to form a cleft through which the mRNA passes as the ribosome moves along it during translation (Fig. 27-14a). The 57 proteins in bacterial ribosomes vary enormously in size and structure. Molecular weights range from about 6,000 to 75,000. Most of the proteins have globular domains arranged on the ribosome surface. Some also have snakelike extensions that protrude into the rRNA core of the ribosome, stabilizing its structure. The functions of some of these proteins have not yet been elucidated in detail, although a structural role seems evident for many of them.

The sequences of the rRNAs of countless thousands of organisms are now known due to genomic sequencing. Each of the three single-stranded rRNAs of *E. coli* has a specific three-dimensional conformation with extensive intrachain base pairing. The folding patterns of the rRNAs are highly conserved in all organisms, particularly the regions implicated in key functions (**Fig. 27-15**). The predicted secondary structure of the rRNAs has largely been confirmed by structural analysis but fails to convey the extensive network of tertiary interactions apparent in the complete structure.

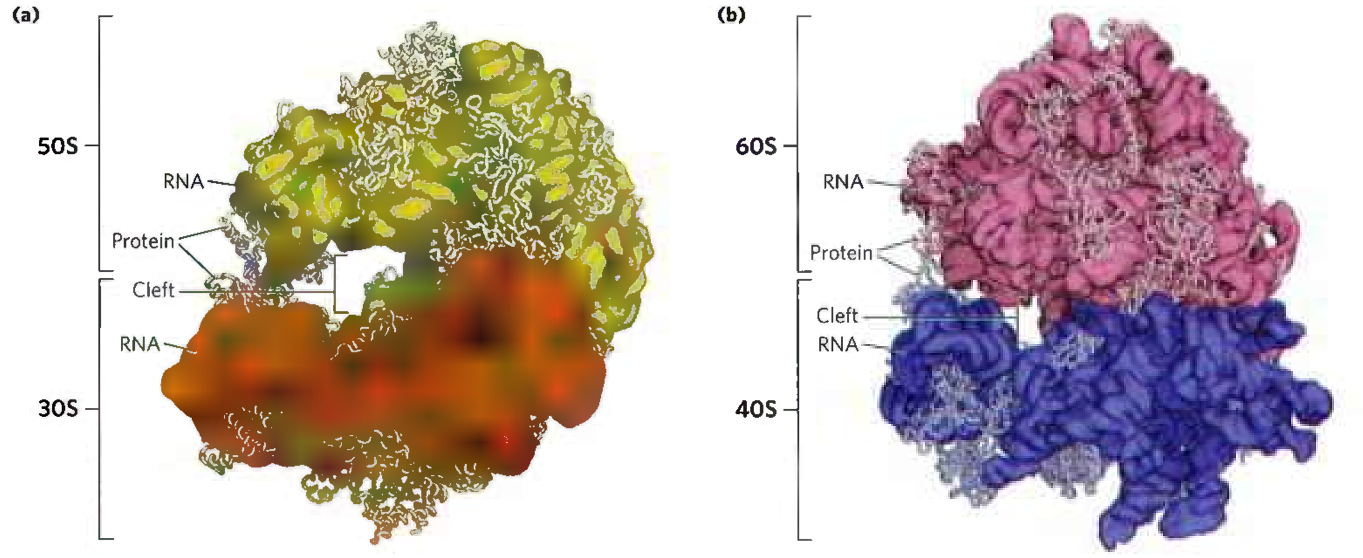

FIGURE 27-14 **The structure of ribosomes.** Our understanding of ribosome structure has been greatly enhanced by multiple high-resolution images of the ribosomes from bacteria and yeast. (a) The bacterial ribosome. The 50S and 30S subunits come together to form the 70S ribosome. The cleft between them is where protein synthesis occurs. (b) The yeast ribosome has a similar structure with somewhat increased complexity. [Data from (a) PDB ID 4V4I, A. Korostelev et al., *Cell* 126:1065, 2006; (b) PDB ID 4V7R, A. FIGURE 27-16 Summary of the composition and mass of ribosomes in bacteria and eukaryotes. The S values associated with the subunits are not additive when subunits are combined, because S values are approximately proportional to the two-thirds power of molecular weight and are also slightly affected by shape.

The ribosomes of eukaryotic cells (other than mitochondrial and chloroplast ribosomes) are larger and more complex than bacterial ribosomes (**Fig. 27-16**; compare Fig. 27-14b), with a diameter of about 23 nm and a sedimentation coefficient of about 80S. They also have two subunits, which vary in size among species but on average are 60S and 40S. Altogether, a ribosome of the yeast *Saccharomyces cerevisiae* contains 79 different proteins and 4 ribosomal RNAs. The ribosomes of mitochondria and chloroplasts are somewhat smaller and simpler than bacterial ribosomes. Nevertheless, ribosomal structure and function are strikingly similar in all organisms and organelles.

In both bacteria and eukaryotes, ribosomes are assembled through a hierarchical incorporation of r-proteins as the rRNAs are synthesized. Much of the processing of pre-rRNAs occurs within large ribonucleoprotein complexes. The composition of these complexes changes as new r-proteins are added, the rRNAs acquire their final form, and some proteins required for rRNA processing dissociate. In eukaryotes, the early stages of assembly occur in the nucleolus, with the final maturation of the ribosome completed after export to the cytosol. P1 Dozens of assembly factors, both proteins and some small RNA molecules (snoRNAs; Fig. 26-24), participate in this process (**Fig. 27-17**).

Transfer RNAs Have Characteristic Structural Features

To understand how tRNAs can serve as adaptors in translating the language of nucleic acids into the language of proteins, we must first examine their structure in more detail. Transfer RNAs are relatively small and consist of a single strand of RNA folded into a precise three-dimensional structure (see Fig. 8-25a). The tRNAs of bacteria and in the cytosol of eukaryotes have between 73 and 93 nucleotide residues, corresponding to molecular weights of 24,000 to 31,000. Mitochondria and chloroplasts contain distinctive, somewhat smaller tRNAs. Cells have at least one kind of tRNA for each amino acid; at least 32 tRNAs are required to recognize all the amino acid codons (some recognize more than one codon), but some cells use more than 32.

Yeast alanine tRNA (tRNA^{Ala}) was the first nucleic acid to be completely sequenced, by Robert Holley in 1965. It contains 76 nucleotide residues, 10 of which have modified bases. Comparisons of tRNAs from various species have revealed many common structural features (**Fig. 27-18a**). Eight or more of the nucleotide residues have modified bases and sugars, many of which are methylated derivatives of the principal bases. Most tRNAs have a guanylate (pG) residue at the 5′ end, and all have the trinucleotide sequence CCA(3′) at the

FIGURE 27-17 Assembly of ribosomes in eukaryotes. ❶ Most of the early steps of ribosome assembly occur in the nucleolus, an organelle inside the nucleus. Ribonucleases and specialized RNAs, including some snoRNAs, process the initial rRNA transcript. ❷ Large pre-ribosomal particles are formed and additional processing of the large complex occurs with the aid of proteins called assembly factors. The pre-40S and pre-60S complexes move into the nucleoplasm. ❸ The 40S and 60S subunits are exported to the cytoplasm, coupled with the ejection of assembly factors. ❹ Final maturation of the ribosome occurs in the cytoplasm.

3′ end. When drawn in two dimensions, all tRNAs have a hydrogen-bonding pattern that forms a cloverleaf structure with four arms, as first proposed by Elizabeth Keller. The longer tRNAs have a short fifth arm, or extra arm. In three dimensions, a tRNA has the form of a twisted L (Fig. 27-18b).

P3 Two of the arms of a tRNA are critical for its adaptor function. The **amino acid arm** can carry a specific

FIGURE 27-18 General structure of tRNAs. (a) The cloverleaf structure. The large dots on the backbone represent nucleotide residues; the blue lines represent base pairs. Characteristic and/or invariant residues common to all tRNAs are specified. Transfer RNAs vary in length from 73 to 93 nucleotides. Extra nucleotides occur in the extra arm or in the D arm. At the end of the anticodon arm is the anticodon loop, which always contains seven unpaired nucleotides. The D arm contains two or three D (5,6-dihydrouridine) residues, depending on the tRNA. In some tRNAs, the D arm has only three hydrogen-bonded base pairs. Pu represents purine nucleotide; Py, pyrimidine nucleotide; ψ, pseudouridylate; G*, guanylate or 2′-*O*-methylguanylate. (b) Schematic diagram of the folded tRNA, which resembles a twisted L.

amino acid esterified by its carboxyl group to the 2′- or 3′-hydroxyl group of the A residue at the 3′ end of the tRNA. The **anticodon arm** contains the anticodon. The other major arms are the **D arm**, which contains the unusual nucleotide dihydrouridine (D), and the **TψC arm**, which contains ribothymidine (T), not usually present in RNAs, and pseudouridine (ψ), which has an unusual carbon–carbon bond between the base and ribose (see Fig. 26-22). The D and TψC arms contribute important interactions for the overall folding of tRNA molecules, and the TψC arm interacts with the large-subunit rRNA.

Having looked at the structures of ribosomes and tRNAs, we now consider in detail the five stages of protein synthesis.

Stage 1: Aminoacyl-tRNA Synthetases Attach the Correct Amino Acids to Their tRNAs

P3 For the synthesis of a polypeptide with a defined sequence, two fundamental chemical requirements must be met: (1) the carboxyl group of each amino acid must be activated to facilitate formation of a peptide bond, and (2) a link must be established between each new amino acid and the information in the mRNA that encodes it. Both these requirements are met by attaching the amino acid to a tRNA in the first stage of protein synthesis. When attached to their amino acid (aminoacylated), the tRNAs are said to be "charged."

This first stage of protein synthesis takes place in the cytosol. Aminoacyl-tRNA synthetases esterify the 20 amino acids to their corresponding tRNAs. Each enzyme is specific for one amino acid and one or more corresponding tRNAs. Most organisms have one aminoacyl-tRNA synthetase for each amino acid. For amino acids with two or more corresponding tRNAs, the same enzyme usually aminoacylates all of them.

In all organisms, the aminoacyl-tRNA synthetases fall into two classes (**Table 27-7**), based on substantial differences in primary and tertiary structure and in reaction mechanism (**Fig. 27-19**). There is no evidence that the two classes share a common ancestor, and the biological, chemical, or evolutionary reasons for two enzyme classes for essentially identical processes remain obscure.

TABLE 27-7 **The Two Classes of Aminoacyl-tRNA Synthetases**

Class I		Class II	
Arg	Leu	Ala	Lys
Cys	Met	Asn	Phe
Gln	Trp	Asp	Pro
Glu	Tyr	Gly	Ser
Ile	Val	His	Thr

Note: Here, Arg represents arginyl-tRNA synthetase, and so forth. The classification applies to all organisms for which tRNA synthetases have been analyzed and is based on protein structural distinctions and on the mechanistic distinction outlined in Figure 27-19.

The reaction catalyzed by an aminoacyl-tRNA synthetase is

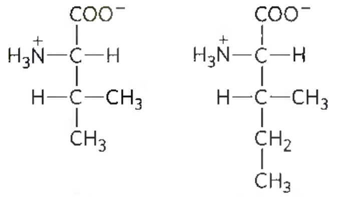
$$\text{Amino acid} + \text{tRNA} + \text{ATP} \xrightarrow{\text{Mg}^{2+}} \text{aminoacyl-tRNA} + \text{AMP} + \text{PP}_i$$

This reaction occurs in two steps in the enzyme's active site. In step ❶ (Fig. 27-19), an enzyme-bound intermediate, aminoacyl adenylate (aminoacyl-AMP), is formed. In the second step, the aminoacyl group is transferred from enzyme-bound aminoacyl-AMP to its corresponding specific tRNA. The course of this second step depends on the class to which the enzyme belongs, as shown by pathways (2a) and (2b) in Figure 27-19. The resulting ester linkage between the amino acid and the tRNA (**Fig. 27-20**) has a highly negative standard free energy of hydrolysis ($\Delta G'^\circ = -29$ kJ/mol). The pyrophosphate formed in the activation reaction undergoes hydrolysis to phosphate by inorganic pyrophosphatase. Thus, *two* high-energy phosphate bonds are ultimately expended for each amino acid molecule activated, rendering the overall reaction for amino acid activation essentially irreversible:

$$\text{Amino acid} + \text{tRNA} + \text{ATP} \xrightarrow{\text{Mg}^{2+}} \text{aminoacyl-tRNA} + \text{AMP} + 2\text{P}_i \qquad \Delta G'^\circ \approx -29 \text{ kJ/mol}$$

Proofreading by Aminoacyl-tRNA Synthetases The aminoacylation of tRNA accomplishes two ends: (1) it activates an amino acid for peptide bond formation and (2) it ensures appropriate placement of the amino acid in a growing polypeptide. The identity of the amino acid attached to a tRNA is not checked on the ribosome, so attachment of the correct amino acid to the tRNA is essential to the fidelity of protein synthesis.

As you will recall from Chapter 6, enzyme specificity is limited by the binding energy available from enzyme-substrate interactions. Discrimination between two similar amino acid substrates has been studied in detail in the case of Ile-tRNA synthetase, which distinguishes between valine and isoleucine, amino acids that differ by only a single methylene group (—CH_2—):



Valine Isoleucine

Ile-tRNA synthetase favors activation of isoleucine (to form Ile-AMP) over valine by a factor of 200 — as we

❶ Carboxyl of amino acid attacks α phosphorus of ATP, forming 5′-aminoacyl adenylate.

②a Aminoacyl group is transferred to the 2′ —OH of the 3′-terminal A residue of tRNA, releasing AMP.

②b Aminoacyl group is transferred directly to the 3′ —OH of the 3′-terminal A residue of tRNA, generating the aminoacyl-tRNA product.

③a Transesterification moves the aminoacyl group to the 3′ —OH of the same tRNA residue, generating the aminoacyl-tRNA product.

MECHANISM FIGURE 27-19 Aminoacylation of tRNA by aminoacyl-tRNA synthetases. Step ❶ is formation of an aminoacyl adenylate, which remains bound to the active site. In the second step, the aminoacyl group is transferred to the tRNA. The mechanism of this step is somewhat different for the two classes of aminoacyl-tRNA synthetases. For class I enzymes, ②a the aminoacyl group is transferred first to the 2′-hydroxyl group of the 3′-terminal A residue, then ③a to the 3′-hydroxyl group by a transesterification reaction. For class II enzymes, ②b the aminoacyl group is transferred directly to the 3′-hydroxyl group of the terminal adenylate.

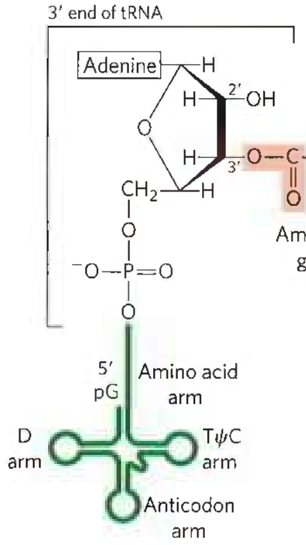

FIGURE 27-20 General structure of aminoacyl-tRNAs. The aminoacyl group is esterified to the 3′ position of the terminal A residue. The ester linkage that both activates the amino acid and joins it to the tRNA is shaded light red.

would expect, given the amount by which a methylene group (in Ile) could enhance substrate binding. Yet valine is erroneously incorporated into proteins in positions normally occupied by an Ile residue at a frequency of only about 1 in 3,000. How is this greater-than-10-fold increase in accuracy brought about? Ile-tRNA synthetase, like some other aminoacyl-tRNA synthetases, has a proofreading function.

Recall a general principle from the discussion of proofreading by DNA polymerases (see Fig. 25-6): if available binding interactions do not provide sufficient discrimination between two substrates, the necessary specificity can be achieved by substrate-specific binding in *two successive* steps. The effect of forcing the system through two successive filters is multiplicative. In the case of Ile-tRNA synthetase, the first filter is the initial binding of the amino acid to the enzyme and its activation to aminoacyl-AMP. The second is the binding of any *incorrect* aminoacyl-AMP products to a separate active site on the enzyme; a substrate that binds in this second active site is hydrolyzed. The R group of valine is slightly smaller than that of isoleucine, so Val-AMP fits the hydrolytic (proofreading) site of the Ile-tRNA synthetase, but Ile-AMP does not. P1 Thus Val-AMP is hydrolyzed to valine and AMP in the proofreading active site, and tRNA bound to the synthetase does not become aminoacylated to the wrong amino acid.

In addition to proofreading after formation of the aminoacyl-AMP intermediate, most aminoacyl-tRNA synthetases can hydrolyze the ester linkage between amino acids and tRNAs in the aminoacyl-tRNAs. This hydrolysis is greatly accelerated for incorrectly charged tRNAs, providing yet a third filter to enhance the fidelity of the overall process. The few aminoacyl-tRNA synthetases that activate amino acids with no close structural relatives (Cys-tRNA synthetase, for example) demonstrate little or no proofreading activity; in these cases, the active site for aminoacylation can sufficiently discriminate between the proper substrate and any incorrect amino acid.

The overall error rate of protein synthesis (~1 mistake per 10^4 amino acids incorporated) is not nearly as low as that of DNA replication. Because flaws in a protein are eliminated when the protein is degraded and are not passed on to future generations, they have less biological significance. The degree of fidelity in protein synthesis is sufficient to ensure that most proteins contain no mistakes and that the large amount of energy required to synthesize a protein is rarely wasted. One defective protein molecule is usually unimportant when many correct copies of the same protein are present.

A “Second Genetic Code” P3 An individual aminoacyl-tRNA synthetase must be specific not only for a single amino acid but for certain tRNAs as well. Discriminating among dozens of tRNAs is just as important for the overall fidelity of protein biosynthesis as is distinguishing among amino acids. The interaction between aminoacyl-tRNA synthetases and tRNAs has been referred to as the “second genetic code,” reflecting its critical role in maintaining the accuracy of protein synthesis. The “coding” rules appear to be more complex than those in the “first” code.

Figure 27-21 summarizes what we know about the nucleotides involved in recognition by some aminoacyl-tRNA synthetases. Some nucleotides are conserved in all tRNAs and therefore cannot be used for discrimination. Nucleotide positions necessary for discrimination by the aminoacyl-tRNA synthetases seem to be concentrated in the amino acid arm and the anticodon arm, including the nucleotides of the anticodon itself. A few are located in other parts of the tRNA molecule. Determination of the crystal structures of aminoacyl-tRNA synthetases complexed with their cognate tRNAs and ATP has added a great deal to our understanding of these interactions (**Fig. 27-22**).

Ten or more specific nucleotides may be involved in recognition of a tRNA by its specific aminoacyl-tRNA synthetase. But in a few cases the recognition mechanism is quite simple. Across a range of organisms from bacteria to humans, the primary determinant of tRNA recognition by the Ala-tRNA synthetases is a single G═U base pair in the amino acid arm of tRNA^{Ala} (**Fig. 27-23a**). A short synthetic RNA with as few as 7 bp arranged in a simple hairpin minihelix is efficiently aminoacylated by the Ala-tRNA synthetase, as long as the RNA contains the critical G═U (Fig. 27-23b). This relatively simple alanine system may be an evolutionary relic of a period when RNA oligonucleotides, ancestors to tRNA, were aminoacylated in a primitive system for protein synthesis.

Steitz, *Biochemistry* 35:14,725, 1996; (b, c (right)) PDB ID 1ASZ, J. Cavarelli et al., *EMBO J.* 13:327, 1994.]

The interaction of aminoacyl-tRNA synthetases and their cognate tRNAs is critical to accurate reading of the genetic code. Any expansion of the code to include new amino acids would necessarily require a new aminoacyl-tRNA synthetase–tRNA pair. A limited expansion of the genetic code has been observed in nature; a more extensive expansion has been accomplished in the laboratory (**Box 27-2**).

Stage 2: A Specific Amino Acid Initiates Protein Synthesis

Protein synthesis begins at the amino-terminal end and proceeds by the stepwise addition of amino acids to the carboxyl-terminal end of the growing polypeptide. The AUG initiation codon thus specifies an *amino-terminal* methionine residue. Although methionine has only one

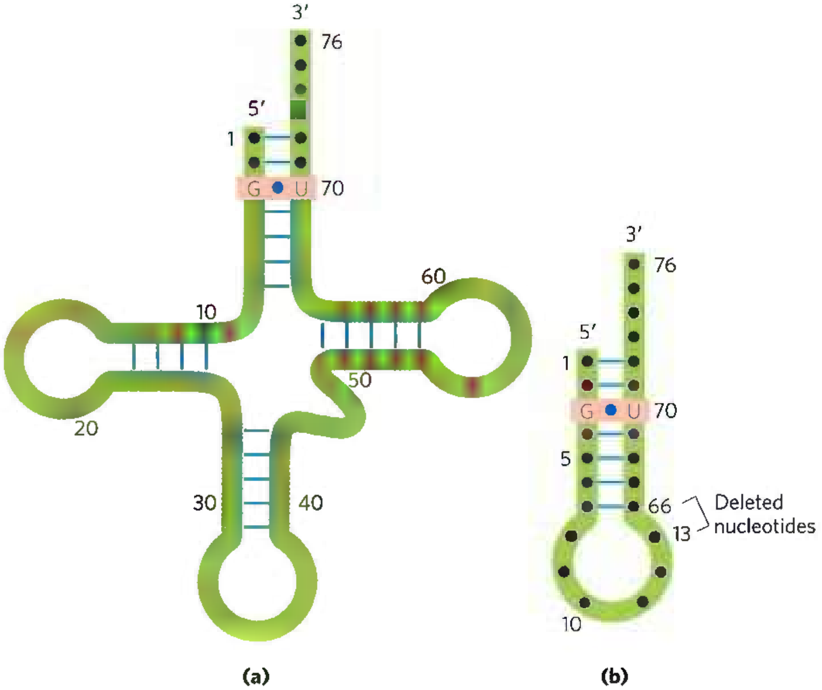

FIGURE 27-23 Structural elements of tRNA^{Ala} that are required for recognition by Ala-tRNA synthetase. (a) The tRNA^{Ala} structural elements recognized by the Ala-tRNA synthetase are unusually simple. A single G=U base pair (light red) is the only element needed for specific binding and aminoacylation. (b) A short synthetic RNA minihelix, with the critical G=U base pair but lacking most of the remaining tRNA structure. This is aminoacylated specifically with alanine almost as efficiently as the complete tRNA^{Ala}.

codon, (5′)AUG, all organisms have two tRNAs for methionine. One is used exclusively when (5′)AUG is the initiation codon for protein synthesis. The other is used to code for a Met residue in an internal position in a polypeptide.

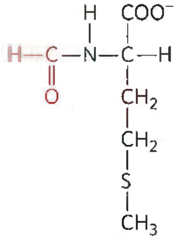
The distinction between an initiating (5′)AUG and an internal one is straightforward. In bacteria, the two types of tRNA specific for methionine are designated tRNA^{Met} and $\text{tRNA}^{\text{fMet}}$. The amino acid incorporated in response to the (5′)AUG initiation codon is *N*-formylmethionine (fMet). It arrives at the ribosome as *N*-formylmethionyl-$\text{tRNA}^{\text{fMet}}$ (fMet-$\text{tRNA}^{\text{fMet}}$), which is formed in two successive reactions. First, methionine is attached to $\text{tRNA}^{\text{fMet}}$ by the Met-tRNA synthetase (which in *E. coli* aminoacylates both $\text{tRNA}^{\text{fMet}}$ and tRNA^{Met}):

$$\text{Methionine} + \text{tRNA}^{\text{fMet}} + \text{ATP} \longrightarrow \text{Met-tRNA}^{\text{fMet}} + \text{AMP} + \text{PP}_i$$

Next, a transformylase transfers a formyl group from N^{10}-formyltetrahydrofolate to the amino group of the Met residue:

$$N^{10}\text{-Formyltetrahydrofolate} + \text{Met-tRNA}^{\text{fMet}} \longrightarrow \text{tetrahydrofolate} + \text{fMet-tRNA}^{\text{fMet}}$$

The transformylase is more selective than the Met-tRNA synthetase; it is specific for Met residues attached to $\text{tRNA}^{\text{fMet}}$, presumably recognizing some unique structural feature of that tRNA. By contrast, Met-$\text{tRNA}^{\text{fMet}}$ inserts methionine in interior positions in polypeptides.



N-Formylmethionine

Addition of the *N*-formyl group to the amino group of methionine by the transformylase prevents fMet from entering interior positions in a polypeptide while also allowing fMet-$\text{tRNA}^{\text{fMet}}$ to be bound at a specific ribosomal initiation site that accepts neither Met-tRNA^{Met} nor any other aminoacyl-tRNA.

In eukaryotic cells, all polypeptides synthesized by cytosolic ribosomes begin with a Met residue (rather than fMet), but, again, the cell uses a specialized initiating tRNA that is distinct from the tRNA^{Met} used at (5′)AUG codons at interior positions in the mRNA. Polypeptides synthesized by mitochondrial and chloroplast ribosomes, however, begin with *N*-formylmethionine. This strongly supports the view that mitochondria and chloroplasts originated from bacterial ancestors that were symbiotically incorporated into precursor eukaryotic cells at an early stage of evolution (see Fig. 1-37).

How can the single (5′)AUG codon determine whether a starting *N*-formylmethionine (or methionine, in eukaryotes) or an interior Met residue is ultimately inserted? The details of the initiation process provide the answer.

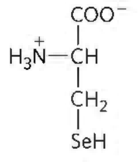
BOX 27-2

Natural and Unnatural Expansion of the Genetic Code

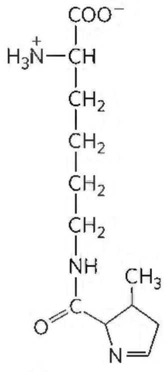
As we have seen, the 20 standard amino acids found in proteins offer only limited chemical functionality. Living systems generally overcome these limitations by using enzymatic cofactors or by modifying particular amino acids after they have been incorporated into proteins. In principle, expansion of the genetic code to introduce new amino acids into proteins offers another route to new functionality, but it is a very difficult route to exploit. Such a change might just as easily result in inactivation of thousands of cellular proteins.

Expanding the genetic code to include a new amino acid requires several cellular changes. A new aminoacyl-tRNA synthetase must generally be present, along with a cognate tRNA. Both of these components must be highly specific, interacting only with each other and the new amino acid. Significant concentrations of the new amino acid must be present in the cell, which may entail the evolution of new metabolic pathways. As outlined in Box 27-1, the anticodon on the tRNA would most likely pair with a codon that usually specifies termination. Making all of this work in a living cell seems unlikely, but it has happened both in nature and in the laboratory.

There are actually 22 rather than 20 amino acids specified by the known genetic code. The two extra amino acids are selenocysteine and pyrrolysine, each found in only very few proteins but both offering a glimpse into the intricacies of code evolution.



Selenocysteine



Pyrrolysine

A few proteins in all cells (such as formate dehydrogenase in bacteria and glutathione peroxidase in mammals) require selenocysteine for their activity. In *E. coli*, selenocysteine is introduced into the enzyme formate dehydrogenase during translation, in response to an in-frame UGA codon. A special type of Ser-tRNA, present at lower levels than other Ser-tRNAs, recognizes UGA and no other codons. This tRNA is charged with serine by the normal serine aminoacyl-tRNA synthetase, and the serine is enzymatically converted to selenocysteine by a separate enzyme before its use at the ribosome. The charged tRNA does not recognize just any UGA codon; some contextual signal in the mRNA, still to be identified, ensures that this tRNA recognizes only the few UGA codons, within certain genes, that specify selenocysteine. In effect, UGA doubles as a codon for both termination and (very occasionally) selenocysteine. This particular code expansion has a dedicated tRNA, as described above, but it lacks a dedicated cognate aminoacyl-tRNA synthetase. The process works for selenocysteine, but one might consider it an intermediate step in the evolution of a complete new codon definition.

Pyrrolysine is found in a group of anaerobic archaea called methanogens (see Box 22-1). These organisms produce methane as a required part of their metabolism, and the Methanosarcinaceae family can use methylamines as substrates for methanogenesis. Producing methane from monomethylamine requires the enzyme monomethylamine methyltransferase. The gene encoding this enzyme has an in-frame UAG termination codon. The structure of the methyltransferase was elucidated in 2002, revealing the presence of the novel amino acid pyrrolysine at the position specified by the UAG codon. Subsequent experiments demonstrated that — unlike selenocysteine — pyrrolysine is attached directly to a dedicated tRNA by a cognate pyrrolysyl-tRNA synthetase. These methanogens produce pyrrolysine via a metabolic pathway that remains to be elucidated. The overall system has all the hallmarks of an established codon assignment, although it works only for UAG codons in this particular gene. As in the case of selenocysteine, there are probably contextual signals that direct this tRNA to the correct UAG codon.

Can scientists match this evolutionary feat? Modification of proteins with various functional groups can provide important insights into the activity and/or structure of the proteins. However, protein modification is often laborious. For example, an investigator who wishes to attach a new group to a particular Cys residue will have to somehow block other Cys residues that may be present on the same protein. If one could instead adapt the genetic code to enable a cell to insert a modified amino acid at a particular location in a protein, the process could be rendered much more convenient. Peter Schultz and coworkers have done just that.

To develop a new codon assignment, one again needs a new aminoacyl-tRNA synthetase and a novel cognate tRNA, both adapted to work only with a particular new amino acid. Efforts to create such an "unnatural" code expansion initially focused on *E. coli*. The codon UAG was chosen as the best target for encoding a new amino acid. UAG is the least used of the three termination codons, and strains with tRNAs selected

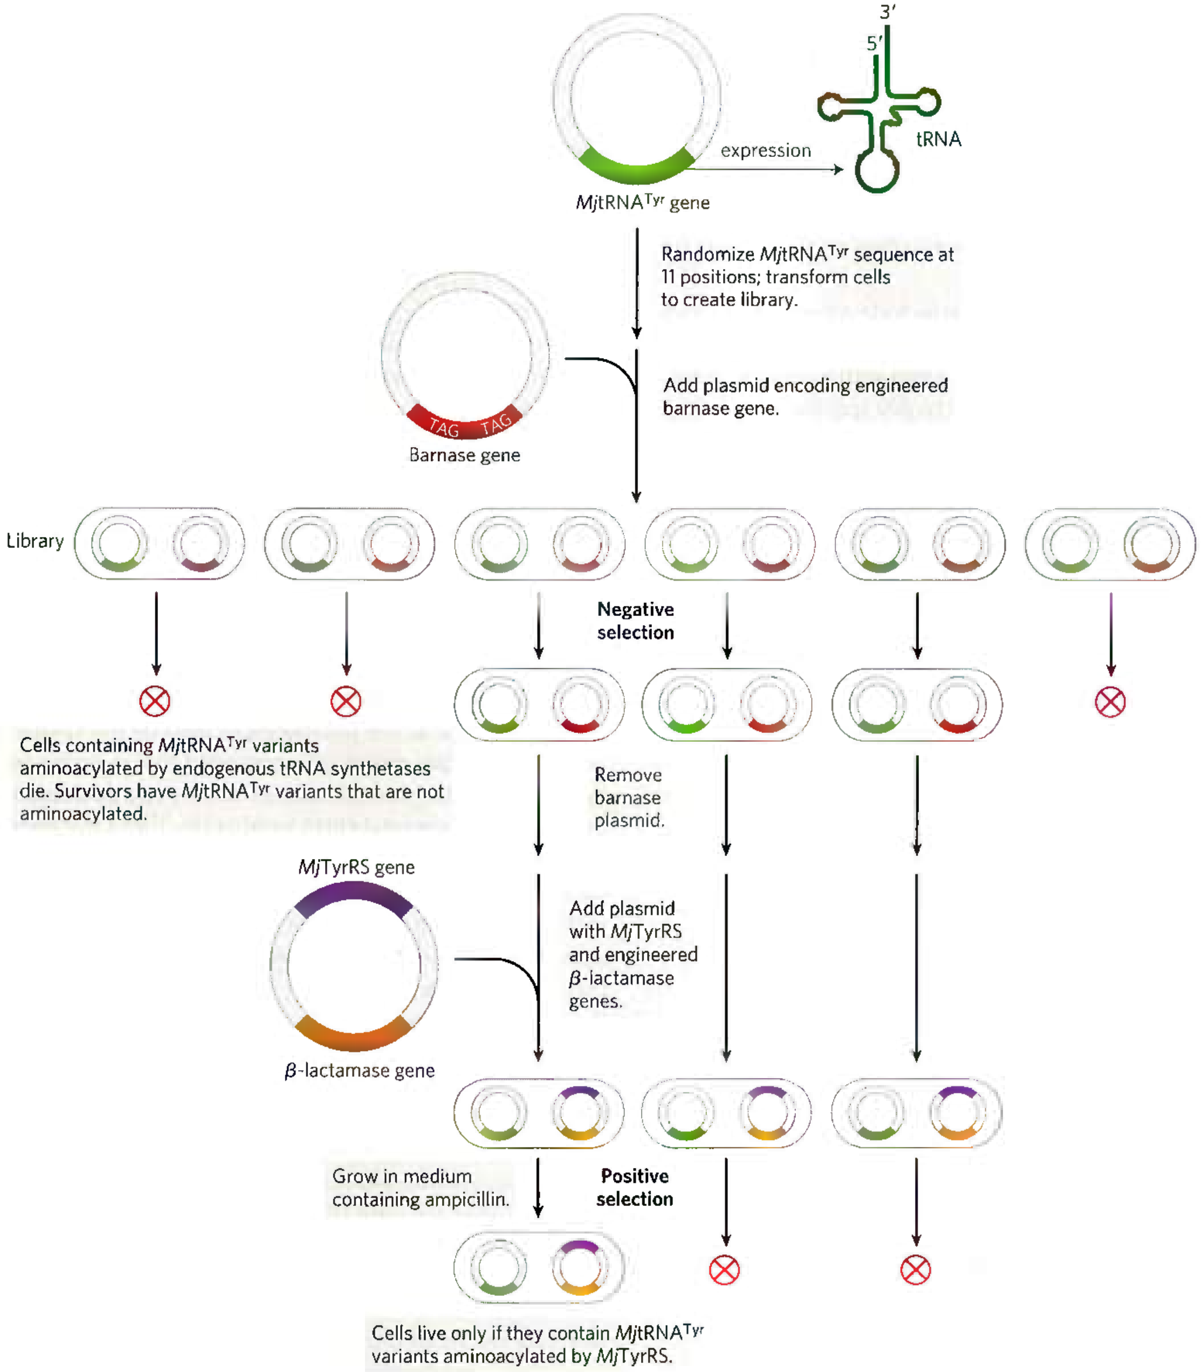
Natural and Unnatural Expansion of the Genetic Code (*Continued*)



Randomize *Mj*tRNA$^{\text{Tyr}}$ sequence at 11 positions; transform cells to create library.

Add plasmid encoding engineered barnase gene.

Cells containing *Mj*tRNA$^{\text{Tyr}}$ variants aminoacylated by endogenous tRNA synthetases die. Survivors have *Mj*tRNA$^{\text{Tyr}}$ variants that are not aminoacylated.

Remove barnase plasmid.

Add plasmid with *Mj*TyrRS and engineered β-lactamase genes.

Grow in medium containing ampicillin.

Cells live only if they contain *Mj*tRNA$^{\text{Tyr}}$ variants aminoacylated by *Mj*TyrRS.

FIGURE 1 Selecting *Mj*tRNA$^{\text{Tyr}}$ variants that function only with the tyrosyl-tRNA synthetase *Mj*TyrRS. The sequence of the gene encoding *Mj*tRNA$^{\text{Tyr}}$, on a plasmid, is randomized at 11 positions that do not interact with *Mj*TyrRS (red dots). The mutagenized plasmids are introduced into *E. coli* cells to create a library of millions of *Mj*tRNA$^{\text{Tyr}}$ variants, represented by the six cells shown here. The toxic barnase gene, engineered to include the sequence TAG so that its transcript includes UAG codons, is present on a separate plasmid, providing a negative selection. If this gene is expressed, the cells die. It can be successfully expressed only if the *Mj*tRNA$^{\text{Tyr}}$ variant expressed by that particular cell is aminoacylated by endogenous (*E. coli*) aminoacyl-tRNA synthetases, inserting an amino acid instead of stopping translation. Another gene, encoding β-lactamase, and also engineered with TAG sequences to produce UAG stop codons, is provided on yet another plasmid that also expresses the gene encoding *Mj*TyrRS. This serves as a means of positive selection for the remaining *Mj*tRNA$^{\text{Tyr}}$ variants. Those variants that are aminoacylated by *Mj*TyrRS allow expression of the β-lactamase gene, so these cells can grow on ampicillin. Multiple rounds of negative and positive selection yield the best *Mj*tRNA$^{\text{Tyr}}$ variants that are aminoacylated uniquely by *Mj*TyrRS and used efficiently in translation.

to recognize UAG do not exhibit growth defects. To create the new tRNA and tRNA synthetase, the genes for a $tRNA^{Tyr}$ and its cognate tyrosyl-tRNA synthetase were taken from the archaeon *Methanococcus jannaschii* (*Mj*$tRNA^{Tyr}$ and *Mj*TyrRS, respectively). *Mj*TyrRS does not bind to the anticodon loop of *Mj*$tRNA^{Tyr}$, so the anticodon loop can be modified to CUA (complementary to UAG) without affecting the interaction. Because the archaeal and bacterial systems are orthologous, the modified archaeal components could be transferred to *E. coli* without disrupting the intrinsic translation system of the bacterial cells.

First, the gene encoding *Mj*$tRNA^{Tyr}$ had to be modified to generate an ideal product tRNA—one that was not recognized by any aminoacyl-tRNA synthetases endogenous to *E. coli* but was aminoacylated by *Mj*TyrRS. Finding such a variant could be accomplished through a series of negative and positive selection cycles designed to efficiently sift through variants of the tRNA gene (Fig. 1). Parts of the *Mj*$tRNA^{Tyr}$ sequence were randomized, allowing creation of a library of cells that each expressed a different version of the tRNA. A gene encoding barnase (a ribonuclease toxic to *E. coli*) was engineered so that its mRNA transcript contained several UAG codons, and this gene was also introduced into the cells on a plasmid. If the *Mj*$tRNA^{Tyr}$ variant expressed in a particular cell in the library were aminoacylated by an endogenous tRNA synthetase, it would express the barnase gene and that cell would die (negative selection). Surviving cells would contain tRNA variants that were not aminoacylated by endogenous tRNA synthetases, but could potentially be aminoacylated by *Mj*TyrRS. A positive selection (Fig. 1) was then set up by engineering the β-lactamase gene (which confers resistance to the antibiotic ampicillin) so that its transcript contained several UAG codons, and introducing this gene into the cells along with the gene encoding *Mj*TyrRS. Those *Mj*$tRNA^{Tyr}$ variants that could be aminoacylated by *Mj*TyrRS allowed growth on ampicillin only when *Mj*TyrRS was also expressed in the cell. Several rounds of this negative and positive selection scheme identified a new *Mj*$tRNA^{Tyr}$ variant that was not affected by endogenous enzymes, was aminoacylated by *Mj*TyrRS, and functioned well in translation.

Next, the *Mj*TyrRS had to be modified to recognize the new amino acid. The gene encoding *Mj*TyrRS was mutagenized to create a large library of variants. Variants that would aminoacylate the new *Mj*$tRNA^{Tyr}$ variant with endogenous amino acids were eliminated using the barnase gene selection. A second positive selection (similar to the ampicillin selection described above) was carried out so that cells would survive only if the *Mj*$tRNA^{Tyr}$ variant were aminoacylated only in the presence of the unnatural amino acid. Several rounds of negative and positive selection generated a cognate tRNA synthetase–tRNA pair that recognized only the unnatural amino acid.

Using this approach, researchers have constructed many *E. coli* strains, each capable of incorporating one particular unnatural amino acid into a protein in response to a UAG codon. The same approach has been used to artificially expand the genetic code of yeast and even mammalian cells. More than 30 different amino acids (Fig. 2) can be introduced site-specifically and efficiently into cloned proteins in this way. The result is an increasingly useful and flexible tool kit with which to advance the study of protein structure and function.

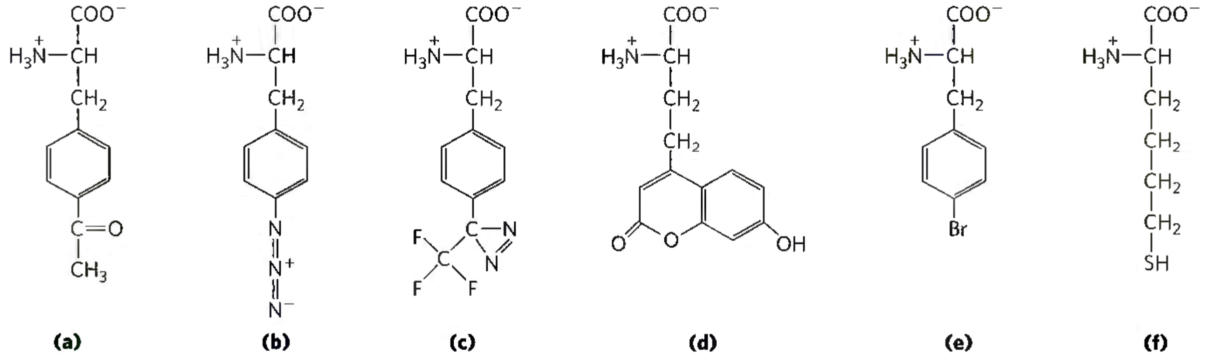


FIGURE 2 A sampling of unnatural amino acids that have been added to the genetic code. These unnatural amino acids add uniquely reactive chemical groups such as (a) a ketone; (b) an azide; (c) a photocrosslinker, a functional group designed to form a covalent bond with a nearby group when activated by light; (d) a highly fluorescent amino acid; (e) an amino acid with a heavy atom (Br) for use in crystallography; and (f) a long-chain cysteine analog that can form extended disulfide bonds. [Information from J. Xie and P. G. Schultz, *Nat. Rev. Mol. Cell Biol.* 7:775, 2006.]

The Three Steps of Initiation The **initiation** of polypeptide synthesis in bacteria requires (1) the 30S ribosomal subunit, (2) the mRNA coding for the polypeptide to be made, (3) the initiating fMet-tRNA$^{\text{fMet}}$, (4) a set of three proteins called initiation factors (IF1, IF2, and IF3), (5) GTP, (6) the 50S ribosomal subunit, and (7) Mg^{2+}. Formation of the initiation complex takes place in three steps (**Fig. 27-24**).

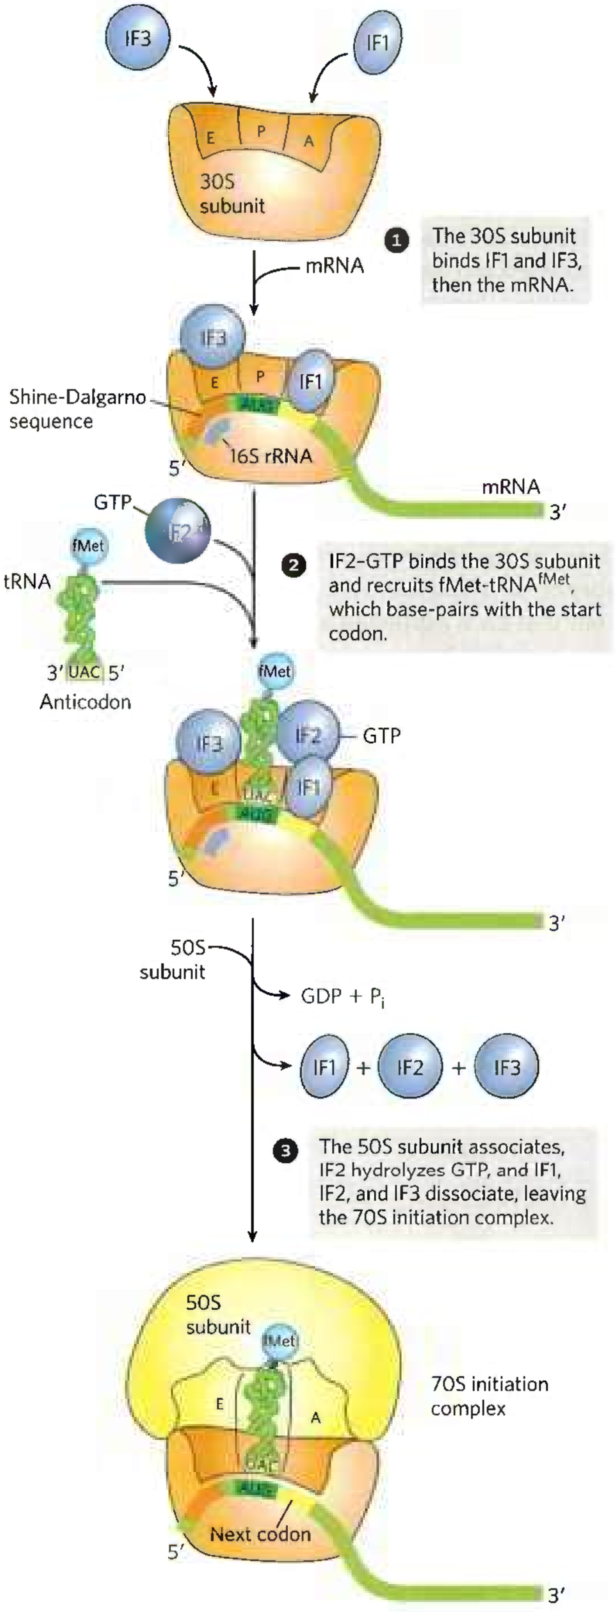
In step ①, the 30S ribosomal subunit binds two initiation factors, IF1 and IF3. Factor IF3 prevents the 30S and 50S subunits from combining prematurely. The mRNA then binds to the 30S subunit. The initiating (5′)AUG is guided to its correct position by the **Shine-Dalgarno sequence** (named for Australian researchers John Shine and Lynn Dalgarno, who identified it) in the mRNA. This consensus sequence is an initiation signal of four to nine purine residues, 8 to 13 bp to the 5′ side of the initiation codon (**Fig. 27-25a**). The sequence base-pairs with a complementary pyrimidine-rich sequence near the 3′ end of the 16S rRNA of the 30S ribosomal subunit (Fig. 27-25b). This mRNA-rRNA interaction positions the initiating (5′)AUG sequence of the mRNA in the precise position on the 30S subunit where it is required for initiation of translation. The particular (5′)AUG where fMet-tRNA$^{\text{fMet}}$ is to be bound is distinguished from other methionine codons by its proximity to the Shine-Dalgarno sequence in the mRNA.

Bacterial ribosomes have three sites that bind tRNAs, the **aminoacyl (A) site**, the **peptidyl (P) site**, and the **exit (E) site**. The A and P sites bind aminoacyl-tRNAs, whereas the E site binds only uncharged tRNAs that have completed their task on the ribosome. Factor IF1 binds at the A site and prevents tRNA binding at this site during initiation. The initiating (5′)AUG is positioned at the P site, the only site to which fMet-tRNA$^{\text{fMet}}$ can bind (Fig. 27-24). The fMet-tRNA$^{\text{fMet}}$ is the only aminoacyl-tRNA that binds first to the P site; during the subsequent elongation stage, all other incoming aminoacyl-tRNAs (including the Met-tRNA$^{\text{fMet}}$ that binds to interior AUG codons) bind first to the A site and only subsequently to the P and E sites. The E site is the site from which the "uncharged" tRNAs leave during elongation. Both the 30S and the 50S subunits contribute to the characteristics of the A and P sites, whereas the E site is largely confined to the 50S subunit.

In step ② of the initiation process (Fig. 27-24), the complex consisting of the 30S ribosomal subunit, IF3, and mRNA is joined by both GTP-bound IF2 and the initiating fMet-tRNA$^{\text{fMet}}$. The anticodon of this tRNA now pairs correctly with the mRNA's initiation codon.

In step ③, this large complex combines with the 50S ribosomal subunit; simultaneously, the GTP bound to IF2 is hydrolyzed to GDP and P_i, which are released from the complex. All three initiation factors leave the ribosome at this point.

P1 Completion of the steps in Figure 27-24 produces a functional 70S ribosome called the **initiation complex**,



① The 30S subunit binds IF1 and IF3, then the mRNA.

② IF2-GTP binds the 30S subunit and recruits fMet-tRNA$^{\text{fMet}}$, which base-pairs with the start codon.

③ The 50S subunit associates, IF2 hydrolyzes GTP, and IF1, IF2, and IF3 dissociate, leaving the 70S initiation complex.

FIGURE 27-24 Formation of the initiation complex in bacteria. The complex forms in three steps (described in the text) at the expense of the hydrolysis of GTP to GDP and P_i. IF1, IF2, and IF3 are initiation factors. E designates the exit site; P, the peptidyl site; and A, the aminoacyl site. Here the anticodon of the tRNA is oriented 3′ to 5′, left to right, as in Figure 27-8, but opposite to the orientation in Figures 27-21 and 27-23.

FIGURE 27-25 Messenger RNA sequences that serve as signals for initiation of protein synthesis in bacteria. (a) Alignment of the initiating AUG (shaded in green) at its correct location on the 30S ribosomal subunit depends in part on upstream Shine-Dalgarno sequences (light red). Portions of the mRNA transcripts of five bacterial genes are shown. Note the unusual example of the *E. coli* LacI protein, which initiates with a GUG (Val) codon. In *E. coli*, AUG is the start codon in approximately 91% of genes, with GUG (7%) and UUG (2%) assuming this role more rarely. (b) The Shine-Dalgarno sequence of the mRNA pairs with a sequence near the 3′ end of the 16S rRNA.

containing the mRNA and the initiating fMet-tRNA$^{\text{fMet}}$. The correct binding of the fMet-tRNA$^{\text{fMet}}$ to the P site in the complete 70S initiation complex is ensured by at least three points of recognition and attachment: the codon-anticodon interaction involving the initiation AUG fixed in the P site, the interaction between the Shine-Dalgarno sequence in the mRNA and the 16S rRNA, and the binding interactions between the ribosomal P site and the fMet-tRNA$^{\text{fMet}}$. The initiation complex is now ready for elongation.

Initiation in Eukaryotic Cells Translation is generally similar in eukaryotic and bacterial cells; most of the significant differences are in the number of components and the mechanistic details. The initiation process in eukaryotes is outlined in **Figure 27-26**. Eukaryotic mRNAs are bound to the ribosome as a complex with a number of specific binding proteins. Eukaryotic cells have at least 12 initiation factors. Initiation factors eIF1A and eIF3 are the functional homologs of the bacterial IF1 and IF3, binding to the 40S subunit in step ①, blocking tRNA binding to the A site and premature joining of the large and small ribosomal subunits, respectively. The factor eIF1 binds to the E site. The charged initiator tRNA is bound by the initiation factor eIF2, which also has bound GTP. In step ②, this ternary complex binds to the 40S ribosomal subunit, along with two other proteins involved in later steps, eIF5 (not shown in Fig. 27-26) and eIF5B. This creates a 43S preinitiation complex. The mRNA binds to the eIF4F complex, which, in step ③, mediates its association with the 43S preinitiation complex. The eIF4F complex is made up of eIF4E (binding to the 5′ cap), eIF4A (an ATPase and RNA helicase), and eIF4G (a linker protein). The eIF4G protein binds to eIF3 and eIF4E to provide the first link between the 43S preinitiation complex and the mRNA. The eIF4G also binds to the poly(A) binding protein (PABP) at the 3′ end of the mRNA, circularizing the mRNA (**Fig. 27-27**) and facilitating the translational regulation of gene expression, as described in Chapter 28.

Addition of the mRNA and its associated factors creates a 48S complex. This complex scans the bound mRNA, starting at the 5′ cap, until an AUG codon is encountered. The scanning process (step ④ in Fig. 27-26) may be facilitated by the RNA helicase of eIF4A, which unwinds RNA secondary structures while in a transient complex with another factor, eIF4B (not shown in Fig. 27-26).

Once the initiating AUG site is encountered, the 60S ribosomal subunit associates with the complex in step ⑤, which is accompanied by release of many of the initiation factors. This requires the activity of eIF5 and eIF5B. The eIF5 protein promotes the GTPase activity of eIF2, producing an eIF2-GDP complex with reduced affinity for the initiator tRNA. The eIF5B protein is homologous to the bacterial IF2. It hydrolyzes its bound GTP and triggers dissociation of eIF2-GDP and other initiation factors, followed closely by association of the 60S subunit. This completes formation of the initiation complex.

FIGURE 27-26 Initiation of protein synthesis in eukaryotes. The five steps are described in the text. Eukaryotic initiation factors mediate the association of, first, the charged initiator tRNA to form a 43S preinitiation complex, and then the mRNA (with the 5′ cap shown in red) to form a 48S complex. The final 80S initiation complex is formed as the 60S subunit associates, coupled with release of most of the initiation factors.

FIGURE 27-27 Circularization of mRNA in the eukaryotic initiation complex. The 3′ and 5′ ends of eukaryotic mRNAs are linked by the eIF4F complex of proteins. The eIF4E subunit binds to the 5′ cap, and the eIF4G protein binds to the poly(A) binding protein (PABP) at the 3′ end of the mRNA. The eIF4G protein also binds to eIF3, linking the circularized mRNA to the 40S subunit of the ribosome.

The roles of the various bacterial and eukaryotic initiation factors in the overall process are summarized in Table 27-8. The mechanism by which these proteins act is an important area of investigation.

Stage 3: Peptide Bonds Are Formed in the Elongation Stage

The third stage of protein synthesis is **elongation**. Again, we begin with bacterial cells. Elongation requires (1) the initiation complex described above, (2) aminoacyl-tRNAs, (3) a set of three soluble cytosolic proteins called **elongation factors** (EF-Tu, EF-Ts, and EF-G in bacteria), and (4) GTP. Cells use three steps to add each amino acid residue, and the steps are repeated as many times as there are residues to be added.

Elongation Step 1: Binding of an Incoming Aminoacyl-tRNA In the first step of the elongation cycle (Fig. 27-28), the

TABLE 27-8 Protein Factors Required for Initiation of Translation in Bacterial and Eukaryotic Cells

Factor	Function
Bacterial	
IF1	Prevents premature binding of tRNAs to A site
IF2	Facilitates binding of fMet-tRNA$^{\text{fMet}}$ to 30S ribosomal subunit
IF3	Binds to 30S subunit; prevents premature association of 50S subunit; enhances specificity of P site for fMet-rRNA$^{\text{fMet}}$
Eukaryotic	
eIF1	Binds to the E site of the 40S subunit; facilitates interaction between eIF2-tRNA-GTP ternary complex and the 40S subunit
eIF1A	Homolog of bacterial IF1; prevents premature binding of tRNAs to A site
eIF2	GTPase; facilitates binding of initiating Met-tRNA$^{\text{Met}}$ to 40S ribosomal subunit
eIF2B[a], eIF3	First factors to bind 40S subunit; facilitate subsequent steps
eIF4F	Complex consisting of eIF4E, eIF4A, and eIF4G
eIF4A	RNA helicase activity; removes secondary structure in the mRNA to permit binding to 40S subunit; part of the eIF4F complex
eIF4B	Binds to mRNA; facilitates scanning of mRNA to locate the first AUG
eIF4E	Binds to the 5′ cap of mRNA; part of the eIF4F complex
eIF4G	Binds to eIF4E and to poly(A) binding protein (PABP); part of the eIF4F complex
eIF5[a]	Promotes dissociation of several other initiation factors from 40S subunit as a prelude to association of 60S subunit to form 80S initiation complex
eIF5b	GTPase homologous to bacterial IF2; promotes dissociation of initiation factors before final ribosome assembly

[a] Not shown in Figure 27-26.

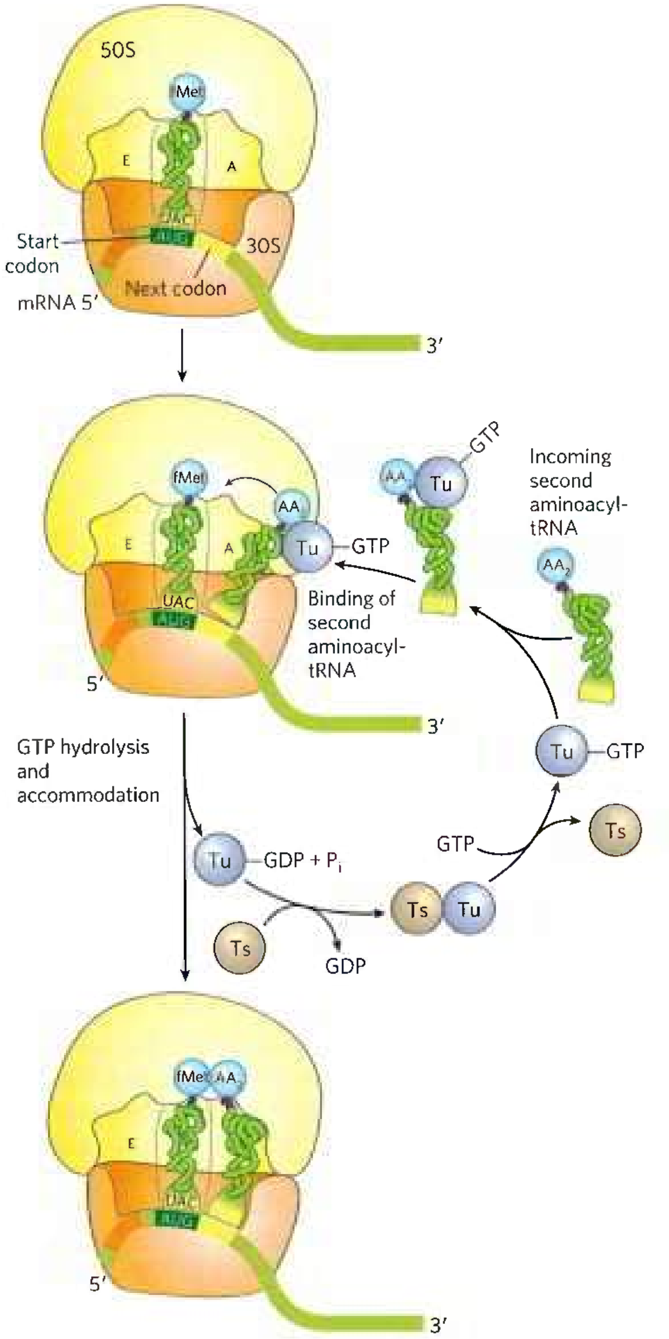

FIGURE 27-28 First elongation step in bacteria: binding of the second aminoacyl-tRNA. The second aminoacyl-tRNA (AA$_2$) enters the A site of the ribosome bound to GTP-bound EF-Tu (shown here as Tu). Binding of the second aminoacyl-tRNA to the A site is accompanied by hydrolysis of the GTP to GDP and P$_i$ and release of the EF-Tu–GDP complex from the ribosome. The EF-Tu–GTP complex is regenerated in a process requiring EF-Ts and GTP. "Accommodation" involves a change in the conformation of the second tRNA that pulls its aminoacyl end into the peptidyl transferase site.

appropriate incoming aminoacyl-tRNA binds to a complex of GTP-bound EF-Tu. The resulting aminoacyl-tRNA–EF-Tu–GTP complex binds to the A site of the 70S initiation complex. The GTP is hydrolyzed and an EF-Tu–GDP complex is released from the 70S ribosome. The bound GDP is released when the EF-Tu–GDP complex binds to EF-Ts, and EF-Ts is subsequently released when another molecule of GTP binds to EF-Tu, recycling it.

Elongation Step 2: Peptide Bond Formation A peptide bond is now formed between the two amino acids bound by their tRNAs to the A and P sites on the ribosome. This occurs by transfer of the initiating *N*-formylmethionyl group from its tRNA to the amino group of the second amino acid, now in the A site (**Fig. 27-29**). The α-amino group of the amino acid in the A site acts as a nucleophile, displacing the tRNA in the P site to form a peptide bond. The constrained structure of the proline side chain interferes with the alignment needed for peptide bonds to form properly. A special system binds to the ribosome to facilitate peptide bonds between two proline residues

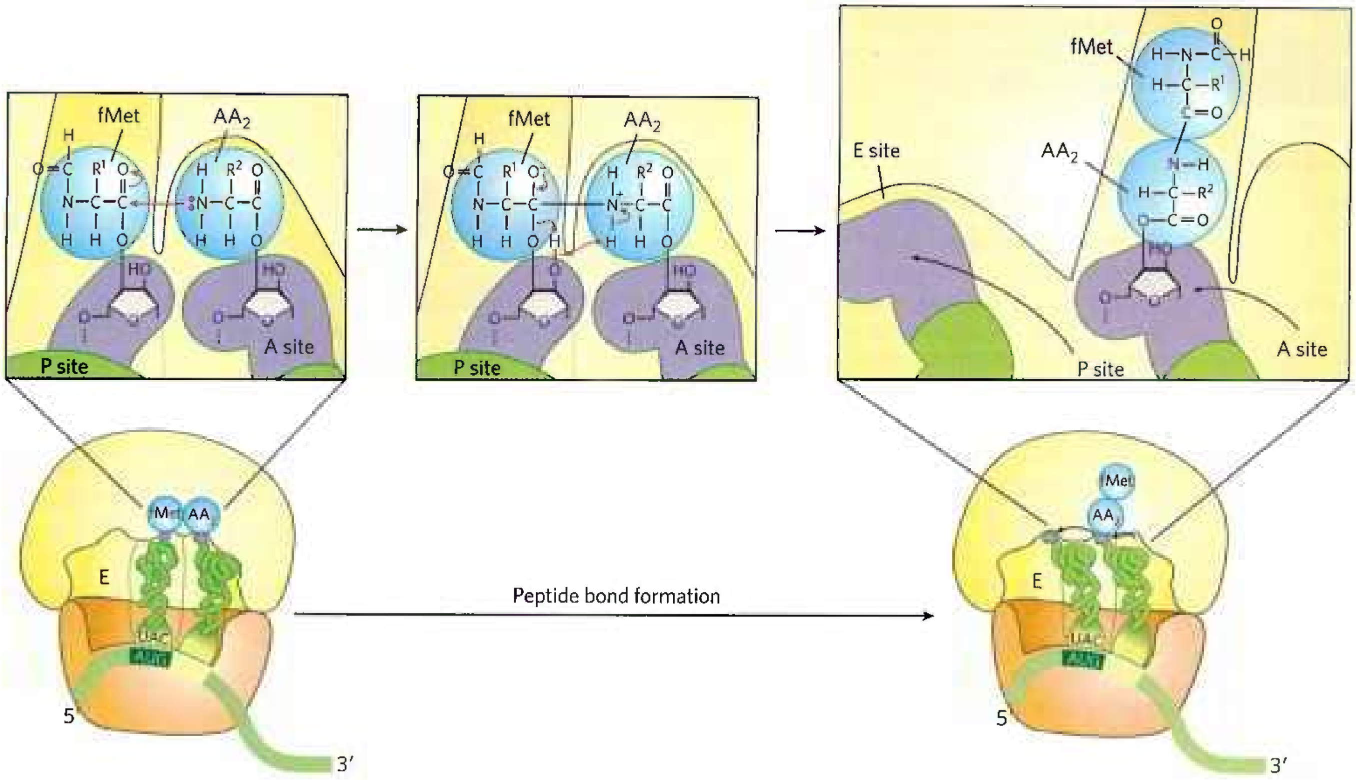

FIGURE 27-29 Second elongation step in bacteria: formation of the first peptide bond. The *N*-formylmethionyl group is transferred to the amino group of the second aminoacyl-tRNA in the A site, forming a dipeptidyl-tRNA. At this stage, both tRNAs bound to the ribosome shift position in the 50S subunit to take up a hybrid binding state. The uncharged tRNA shifts so that its 3′ and 5′ ends are in the E site. Similarly, the 3′ and 5′ ends of the peptidyl-tRNA shift to the P site. The anticodons remain in the P and A sites. Note the involvement of the 2′-hydroxyl group of the 3′-terminal adenosine as a general acid-base catalyst in this reaction.

whenever that is necessary (**Box 27-3**). The reaction produces a dipeptidyl-tRNA in the A site, and the now "uncharged" (deacylated) $tRNA^{fMet}$ remains bound to the P site. The tRNAs then shift to a hybrid binding state, with elements of each spanning two different sites on the ribosome, as shown in Figure 27-29.

P5 The **peptidyl transferase** activity that catalyzes peptide bond formation resides in the 23S rRNA rather than in any of the protein components of ribosomes. The ribosomal 23S rRNA catalyzes the reaction by binding and aligning the tRNAs in the A and P sites in the proper orientations for reaction. A highly conserved active site adenosine residue in the 23S rRNA (A2451 in *E. coli*) may facilitate the reaction by general base catalysis and transition state stabilization utilizing N-3 in the purine ring and/or the 2′-hydroxyl group. This addition to the known catalytic repertoire of ribozymes has interesting implications for the evolution of life (see Section 26.4).

Elongation Step 3: Translocation In the final step of the elongation cycle, **translocation**, the ribosome moves one codon toward the 3′ end of the mRNA (**Fig. 27-30a**). This movement shifts the anticodon of the dipeptidyl-tRNA, which is still attached to the second codon of the mRNA, from the A site to the P site, and shifts the deacylated tRNA from the P site to the E site, from where the tRNA is released into the cytosol. The third codon of the mRNA now lies in the A site and the second codon lies in the P site. Movement of the ribosome along the mRNA requires EF-G (also known as translocase) and the energy provided by hydrolysis of another molecule of GTP. Because the structure of EF-G mimics the structure of the EF-Tu–tRNA complex (Fig. 27-30b), EF-G can bind the A site and, presumably, displace the peptidyl-tRNA.

After translocation, the ribosome, with its attached dipeptidyl-tRNA and mRNA, is ready for the next elongation cycle and attachment of a third amino acid residue. This process occurs in the same way as addition of the second residue (as shown in Figs. 27-28, 27-29, and 27-30). For each amino acid residue correctly added to the growing polypeptide, two GTPs are hydrolyzed to GDP and P_i as the ribosome moves from codon to codon along the mRNA toward the 3′ end.

The polypeptide remains attached to the tRNA of the most recent amino acid to be inserted. This association maintains the functional connection between the information in the mRNA and its decoded polypeptide output. At the same time, the ester linkage between this tRNA and the carboxyl terminus of the growing

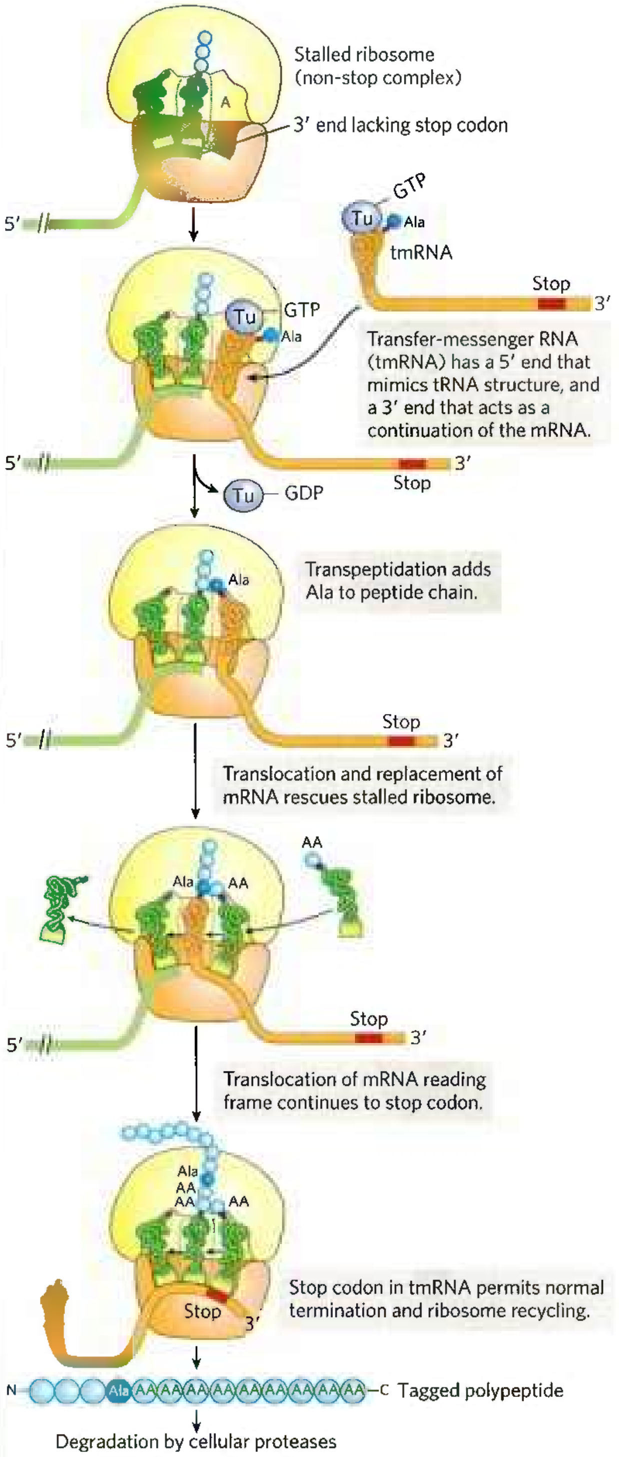
BOX 27-3

Ribosome Pausing, Arrest, and Rescue

Ribosomes may stall during protein biosynthesis, especially while translating an mRNA that is damaged or incomplete. If translation cannot proceed to the end of the gene, the termination factors cannot act, and the ribosome may become "stuck" and thus inactivated.

Translation can experience a variety of stalling events. One well-documented issue involves the addition of proline to the growing chain, particularly when two prolines must be added sequentially. Unlike the other amino acids, proline is a secondary amine and is not as good a nucleophile in the peptide bond formation step (Fig. 27-29). The constrained geometry of the proline side chain can also affect alignment of groups for reaction on the ribosome, an issue particularly acute when the peptide bond is to be between two prolines. Bacteria have an elongation factor P (EFP) that binds between the E and P sites on the ribosome next to the peptidyl-tRNA. EFP binding affects the positioning of adjacent bound tRNAs and facilitates an optimal alignment for peptide bond formation with proline. Ribosomes in cells lacking EFP stall regularly at locations where two or more proline codons must be read consecutively. In eukaryotes, a factor closely related to EFP, eIF5A, performs this same function.

When the ribosome encounters the end of an mRNA before encountering a stop codon, the translocation step leads to formation of a stable **non-stop complex**, in which the A site has no mRNA that can interact with a new charged tRNA. The non-stop complex cannot be recycled by the normal termination factors. Instead, the ribosome is rescued by **trans-translation** (Fig. 1). In virtually all bacteria, the rescue system consists of **transfer-messenger RNA (tmRNA)** and **small protein B (SmpB)**. These bind to the stalled complex in such a way that the tmRNA is positioned in the empty A site so that the ribosome can continue translation until it encounters a stop codon embedded in the tmRNA. The ribosome is then recycled, and both the defective mRNA and the polypeptide translated from it are degraded. Similar systems exist in eukaryotes.



Transfer-messenger RNA (tmRNA) has a 5′ end that mimics tRNA structure, and a 3′ end that acts as a continuation of the mRNA.

Transpeptidation adds Ala to peptide chain.

Translocation and replacement of mRNA rescues stalled ribosome.

Translocation of mRNA reading frame continues to stop codon.

Stop codon in tmRNA permits normal termination and ribosome recycling.

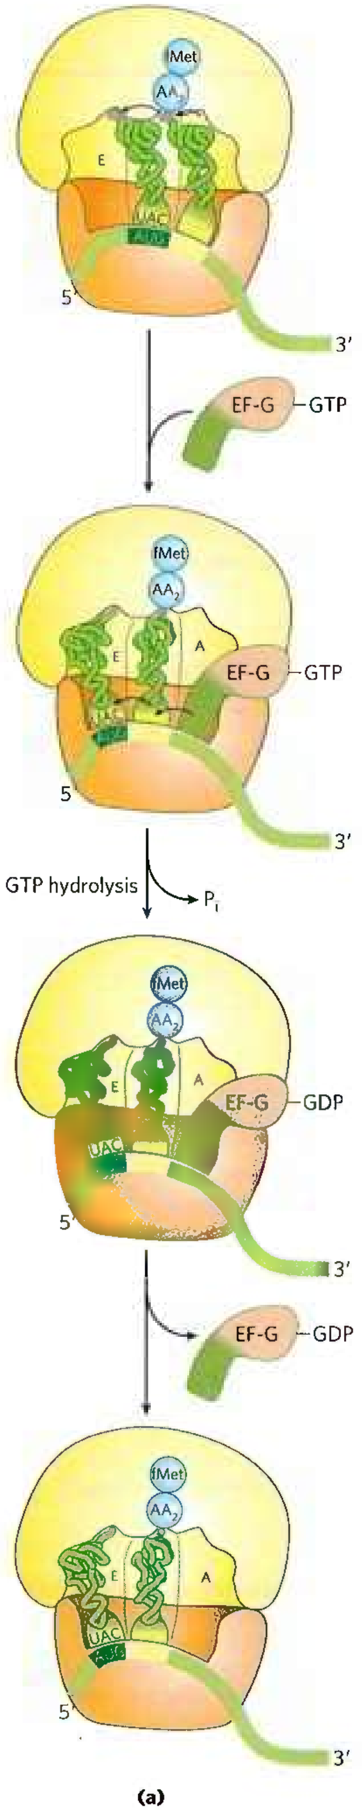
Degradation by cellular proteases

FIGURE 1 Rescue of stalled bacterial ribosomes by tmRNA. In bacteria, tmRNA rescues stalled ribosomes by mimicking both tRNA and mRNA. The multistep pathway permits release and degradation of the damaged mRNA and tags the truncated polypeptide with an abbreviated carboxyl-terminal amino acid sequence that ensures its rapid degradation.

polypeptide activates the terminal carboxyl group for nucleophilic attack by the incoming amino acid to form a new peptide bond (Fig. 27-29). As the existing ester linkage between the polypeptide and tRNA is broken during peptide bond formation, the linkage between the polypeptide and the information in the mRNA persists, because each newly added amino acid is still attached to its tRNA.

The elongation cycle in eukaryotes is similar to that in bacteria. Three eukaryotic elongation factors (eEF1α, eEF1$\beta\gamma$, and eEF2) have functions analogous to those of the bacterial elongation factors (EF-Tu, EF-Ts, and EF-G, respectively). When a new aminoacyl-tRNA binds to the A site, an allosteric interaction leads to ejection of the uncharged tRNA from the E site.

Proofreading on the Ribosome The GTPase activity of EF-Tu during the first step of elongation in bacterial cells (Fig. 27-28) makes an important contribution to the rate and fidelity of the overall biosynthetic process. Both the EF-Tu–GTP and EF-Tu–GDP complexes exist for a few milliseconds before they dissociate. These two intervals provide opportunities for the codon-anticodon interactions to be proofread. Incorrect aminoacyl-tRNAs normally dissociate from the A site during one of these periods. If the GTP analog guanosine



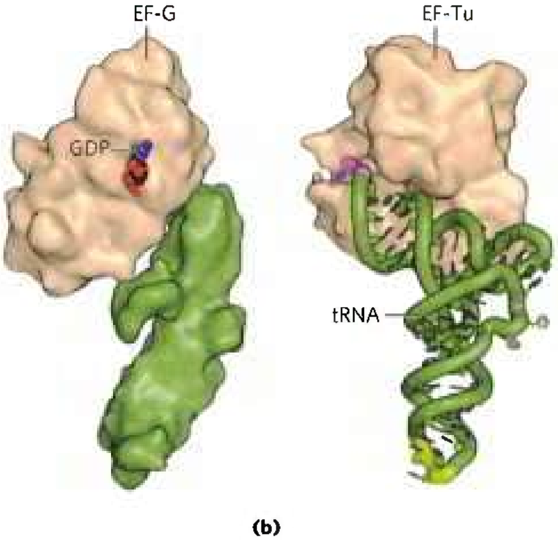


FIGURE 27-30 Third elongation step in bacteria: translocation. (a) The ribosome moves one codon toward the 3′ end of the mRNA, using energy provided by hydrolysis of GTP bound to EF-G (translocase). The dipeptidyl-tRNA is now entirely in the P site, leaving the A site open for an incoming (third) aminoacyl-tRNA. The uncharged tRNA later dissociates from the E site, and the elongation cycle begins again. (b) The structure of EF-G (left) mimics the structure of EF-Tu complexed with tRNA (right). The carboxyl-terminal part of EF-G mimics the structure of the anticodon loop of tRNA in both shape and charge distribution. [(b) Data from (left) PDB ID 1DAR, S. al-Karadaghi et al., *Structure* 4:555, 1996; (right) PDB ID 1B23, P. Nissen et al., *Structure* 7:143, 1999.]

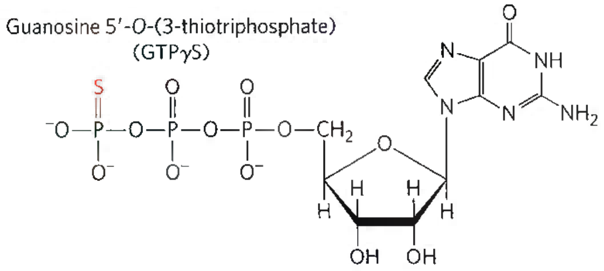
5′-*O*-(3-thiotriphosphate) (GTPγS) is used in place of GTP, hydrolysis is slowed, improving the fidelity (by increasing the proofreading intervals) but reducing the rate of protein synthesis.



Guanosine 5′-*O*-(3-thiotriphosphate)
(GTPγS)

The process of protein synthesis (including the characteristics of codon-anticodon pairing already described) has clearly been optimized through evolution to balance the requirements for speed and fidelity. Improved fidelity might diminish speed, whereas increases in speed would probably compromise fidelity. And, recall that the proofreading mechanism on the ribosome establishes only that the proper codon-anticodon pairing has taken place, not that the correct amino acid is attached to the tRNA. If a tRNA is successfully aminoacylated with the wrong amino acid (as can be done experimentally), this incorrect amino acid is efficiently incorporated into a protein in response to whatever codon is normally recognized by the tRNA.

Stage 4: Termination of Polypeptide Synthesis Requires a Special Signal

Elongation continues until the ribosome adds the last amino acid coded by the mRNA. **Termination**, the fourth stage of polypeptide synthesis, is signaled by the presence of one of three termination codons in the mRNA (UAA, UAG, UGA), immediately following the final coded amino acid. Mutations in a tRNA anticodon that allow an amino acid to be inserted at a termination codon are generally deleterious to the cell. In bacteria, once a termination codon occupies the ribosomal A site, three **termination factors**, or **release factors**—the proteins RF1, RF2, and RF3—contribute to (1) hydrolysis of the terminal peptidyl-tRNA bond; (2) release of the free polypeptide and the last tRNA, now uncharged, from the P site; and (3) dissociation of the 70S ribosome into its 30S and 50S subunits, ready to start a new cycle of polypeptide synthesis (**Fig. 27-31**). RF1 recognizes the termination codons UAG and UAA, and RF2 recognizes UGA and UAA. Either RF1 or RF2 (depending on which codon is present) binds at a termination codon and induces peptidyl transferase to transfer the growing polypeptide to a water molecule rather than to another amino acid. The release factors have domains thought to mimic the structure of tRNA, as shown for the elongation factor EF-G in Figure 27-30b. The specific function of RF3 has not been firmly established, although it is thought to release the ribosomal subunit. In eukaryotes, a single release factor, eRF, recognizes all three termination codons.

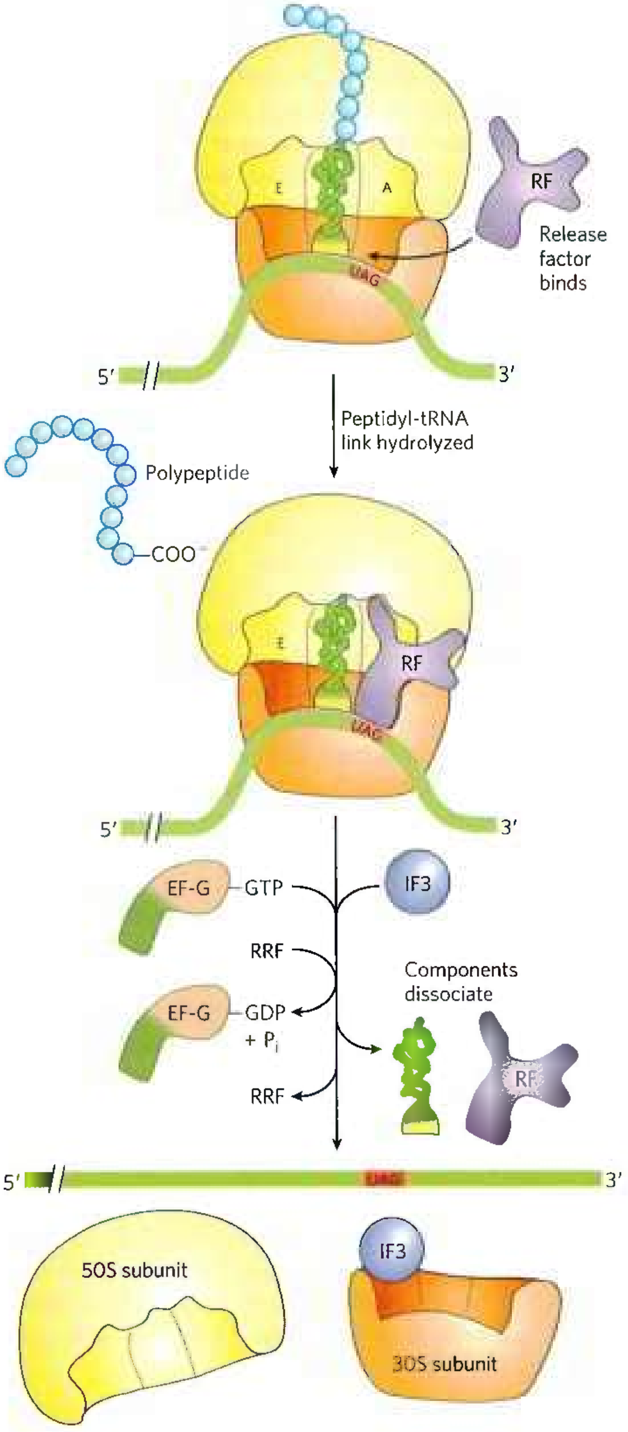


FIGURE 27-31 Termination of protein synthesis in bacteria. Synthesis is terminated in response to a termination codon in the A site. First, a release factor, RF (RF1 or RF2, depending on which termination codon is present), binds to the A site. This leads to hydrolysis of the ester linkage between the nascent polypeptide and the tRNA in the P site and release of the completed polypeptide. Finally, the mRNA, deacylated tRNA, and release factor leave the ribosome, which dissociates into its 30S and 50S subunits, aided by ribosome recycling factor (RRF), IF3, and energy provided by EF-G–mediated GTP hydrolysis. The 30S subunit complex with IF3 is ready to begin another cycle of translation.

Dissociation of the translation components leads to ribosome recycling. The release factors dissociate from the posttermination complex (with an uncharged tRNA in the P site) and are replaced by EF-G and a protein called **ribosome recycling factor (RRF**; M_r 20,300). Hydrolysis of GTP by EF-G leads to dissociation of the 50S subunit from the 30S–tRNA–mRNA complex. EF-G and RRF are replaced by IF3, which promotes dissociation of the tRNA. The mRNA is then released. The complex of IF3 and the 30S subunit is then ready to initiate another round of protein synthesis (Fig. 27-24).

Energy Cost of Fidelity in Protein Synthesis P1 Synthesis of a protein true to the information specified in its mRNA requires energy well beyond what would be required to synthesize peptide bonds linking a random sequence of amino acids. Formation of each aminoacyl-tRNA uses two high-energy phosphate groups. An additional ATP is consumed each time an incorrectly activated amino acid is hydrolyzed by the deacylation activity of an aminoacyl-tRNA synthetase as part of its proofreading activity. A GTP is cleaved to GDP and P_i during the first elongation step, and another during the translocation step. Thus, on average, the energy derived from the hydrolysis of more than four NTPs to NDPs is required for the formation of each peptide bond of a polypeptide.

This represents an exceedingly large thermodynamic "push" in the direction of synthesis: at least 4×30.5 kJ/mol = 122 kJ/mol of phosphodiester bond energy to generate a peptide bond, which has a standard free energy of hydrolysis of only about −21 kJ/mol. The net free-energy change during peptide bond synthesis is thus −101 kJ/mol. Proteins are information-containing polymers. The biochemical goal is not simply the formation of a peptide bond but the formation of a peptide bond between two *specified* amino acids. Each of the high-energy phosphate compounds expended in this process plays a critical role in maintaining proper alignment between each new codon in the mRNA and its associated amino acid at the growing end of the polypeptide. This energy permits very high fidelity in the biological translation of the genetic message of mRNA into the amino acid sequence of proteins.

Rapid Translation of a Single Message by Polysomes Large clusters of 10 to 100 ribosomes that are very active in protein synthesis can be isolated from both eukaryotic and bacterial cells. Electron micrographs show a fiber between adjacent ribosomes in the cluster, which is called a **polysome** (**Fig. 27-32a**). The connecting strand is a single molecule of mRNA that is being translated simultaneously by many closely spaced ribosomes, allowing the highly efficient use of the mRNA.

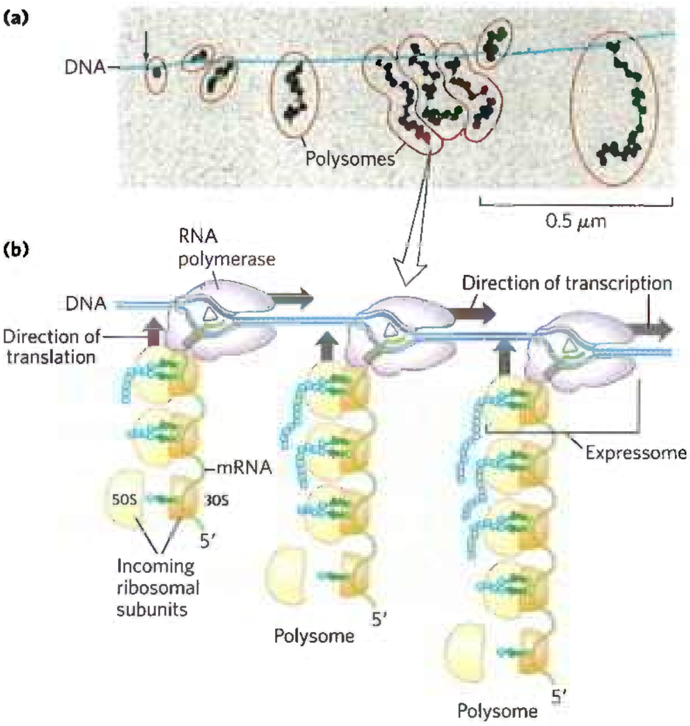

FIGURE 27-32 Coupling of transcription and translation in bacteria. (a) Electron micrograph of polysomes forming during transcription of a segment of DNA from *E. coli*. Each mRNA is being translated by many ribosomes simultaneously. The nascent polypeptide chains are difficult to see under the conditions used to prepare the sample shown here. The arrow marks the approximate beginning of the gene that is being transcribed. (b) Each mRNA is translated by ribosomes while it is still being transcribed from DNA by RNA polymerase. This is possible because the mRNA in bacteria does not have to be transported from a nucleus to the cytoplasm before encountering ribosomes. In this schematic diagram the ribosomes are depicted as smaller than the RNA polymerase. In reality, the ribosomes (M_r 2.7×10^6) are an order of magnitude larger than the RNA polymerase (M_r 3.9×10^5). [(a) O. L. Miller, Jr., et al. *Science* 169:392, 1970, Fig. 3. © 1970 American Association for the Advancement of Science.]

In bacteria, transcription and translation are tightly coupled. Messenger RNAs are synthesized and translated in the same 5′→3′ direction. As soon as the 5′ end of the mRNA appears, ribosomes and the RNA polymerase form a complex, the **expressome**, beginning translation long before transcription is complete (Fig. 27-32b). As the 5′ end of the mRNA exits one ribosome, additional ribosomes are loaded in succession to form a polysome. The situation is quite different in eukaryotic cells, where newly transcribed mRNAs must leave the nucleus before they can be translated (see Fig. 27-17).

Bacterial mRNAs generally exist for just a few minutes (p. 986) before they are degraded by nucleases. To maintain high rates of protein synthesis, the mRNA for a given protein or set of proteins must be made continuously and translated with maximum efficiency. The short lifetime of mRNAs in bacteria allows a rapid cessation of synthesis when the protein is no longer needed.

Stage 5: Newly Synthesized Polypeptide Chains Undergo Folding and Processing

In the final stage of protein synthesis, the nascent polypeptide chain is folded and processed into its biologically active form. During or after its synthesis, the polypeptide progressively assumes its native conformation. As introduced in Chapter 4, protein chaperones, chaperonins, and specific enzymes (e.g., protein disulfide isomerase and peptide prolyl cis-trans isomerase) play an important role in the correct folding of many proteins in all cells. Chaperones and chaperonins, exemplified by GroEL/GroES in bacteria (**Fig. 27-33**) and Hsp60 in eukaryotes, assist folding in part by restricting formation of unproductive aggregates and limiting the conformational space that a polypeptide may explore as it folds. **P4** ATP is hydrolyzed as part of this process. The GroEL/GroES system is required for the folding of about 10%–15% of the proteins in *E. coli*.

Some newly made proteins, bacterial, archaeal, and eukaryotic, do not attain their final biologically active conformation until they have been altered by one or more **posttranslational modifications**. Protein modifications of one type or another have been described in almost every chapter of this text, and some prominent examples are summarized here.

Amino-Terminal and Carboxyl-Terminal Modifications The first residue inserted in all polypeptides is *N*-formylmethionine (in bacteria) or methionine (in eukaryotes). However, the formyl group, the amino-terminal Met residue, and often additional amino-terminal (and, in some cases, carboxyl-terminal) residues may be removed enzymatically in formation of the final functional protein. In as many as 50% of eukaryotic proteins, the amino group of the amino-terminal residue is *N*-acetylated after translation. Carboxyl-terminal residues are also sometimes modified.

Loss of Signal Sequences As we shall see in Section 27.3, the 15 to 30 residues at the amino-terminal end of some proteins play a role in directing the protein to its ultimate destination in the cell. Such **signal sequences** are eventually removed by specific peptidases.

FIGURE 27-33 Chaperonins in protein folding. (a) A proposed pathway for the action of the *E. coli* chaperonins GroEL (a member of the Hsp60 protein family) and GroES. Each GroEL complex consists of two large chambers formed by two heptameric rings (each subunit M_r 57,000). GroES, also a heptamer (subunit M_r 10,000), blocks one of the GroEL chambers after an unfolded protein is bound inside. The chamber with the unfolded protein is referred to as cis; the opposite one is trans. Folding occurs within the cis chamber, during the time it takes to hydrolyze the seven ATP that are bound to the subunits in the heptameric ring. The GroES and the ADP molecules then dissociate, and the protein is released. The two chambers of the GroEL/Hsp60 systems alternate in the binding and facilitated folding of client proteins. (b) A cutaway image of the GroEL/GroES complex. The α-helical secondary structure is represented as cylinders within a transparent surface structure. A folded protein (gp23) is shown within the large interior space of the upper chamber; an unfolded version of gp23 is shown in the lower chamber. [(a) Information from F. U. Hartl et al., *Nature* 475:324, 2011, Fig. 3. (b) Data from EMDB-1548, D. K. Clare et al., *Nature* 457:107, 2009; PDB ID 2CGT, D. K. Clare et al., *J. Mol. Biol.* 358:905, 2006; PDB ID 1YUE, A. Fokine et al., *Proc. Natl. Acad. Sci. USA* 102:7163, 2005.]

are enzymatically phosphorylated by ATP (**Fig. 27-34a**); the phosphate groups add negative charges to these polypeptides. The functional significance of this modification varies from one protein to the next. For example, the milk protein casein has many phosphoserine groups that bind Ca^{2+}. Calcium, phosphate, and amino acids are all valuable to suckling young, so casein efficiently provides three essential nutrients. And as we have seen in numerous instances, phosphorylation-dephosphorylation cycles regulate the activity of many enzymes and regulatory proteins.

Extra carboxyl groups may be added to Glu residues of some proteins. For example, the blood-clotting protein prothrombin contains γ-carboxyglutamate residues (Fig. 27-34b) in its amino-terminal region; the γ-carboxyl groups are introduced by an enzyme that requires vitamin K. These carboxyl groups bind Ca^{2+}, which is required to initiate the clotting mechanism.

Monomethyl- and dimethyllysine residues (Fig. 27-34c) occur in some muscle proteins and in cytochrome *c*. The calmodulin of most species contains one trimethyllysine residue at a specific position. In other proteins, the carboxyl groups of some Glu residues undergo methylation, removing their negative charge.

Attachment of Carbohydrate Side Chains The carbohydrate side chains of glycoproteins are attached covalently during or after synthesis of the polypeptide. In some glycoproteins, the carbohydrate side chain is attached enzymatically to Asn residues (*N*-linked oligosaccharides), in others to Ser or Thr residues (*O*-linked oligosaccharides; see Fig. 7-27). Many proteins that function extracellularly, as well as the lubricating proteoglycans that coat mucous membranes, contain oligosaccharide side chains (see Fig. 7-25).

Addition of Isoprenyl Groups Some eukaryotic proteins are modified by the addition of groups derived from isoprene (isoprenyl groups). A thioether bond is formed between the isoprenyl group and a Cys residue of the protein (see Fig. 11-16). The isoprenyl groups are derived from pyrophosphorylated intermediates of the cholesterol biosynthetic pathway (see Fig. 21-36), such as farnesyl pyrophosphate (**Fig. 27-35**). Proteins modified in this way include the Ras proteins (small G proteins), which are products of the *ras* oncogenes and proto-oncogenes, and the trimeric G proteins (both discussed in Chapter 12), as well as lamins, proteins found in the nuclear matrix. The isoprenyl group helps to anchor the protein in a membrane. The transforming (carcinogenic) activity of the *ras* oncogene is lost when isoprenylation of the Ras protein is blocked, a finding that has stimulated interest in identifying inhibitors of this posttranslational modification pathway for use in cancer chemotherapy.

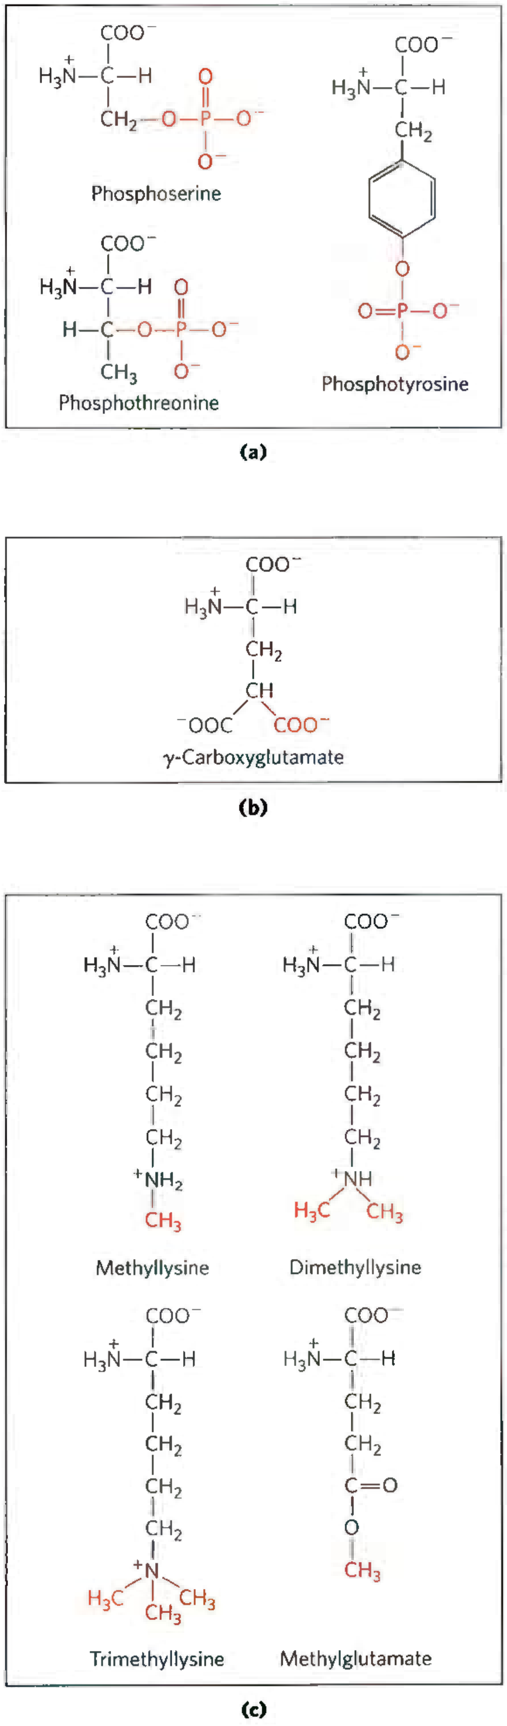

FIGURE 27-34 **Some modified amino acid residues.** (a) Phosphorylated amino acids. (b) A carboxylated amino acid. (c) Some methylated amino acids.

Addition of Prosthetic Groups Many proteins require for their activity covalently bound prosthetic groups. Two examples are the biotin molecule of acetyl-CoA carboxylase and the heme group of hemoglobin or cytochrome *c*.

Proteolytic Processing Many proteins are initially synthesized as large, inactive precursor polypeptides that are proteolytically trimmed to form their smaller, active forms. Examples include proinsulin (Fig. 23-4), some viral proteins (Fig. 26-30), and proteases such as chymotrypsinogen and trypsinogen (Fig. 6-42).

Formation of Disulfide Cross-Links After folding into their native conformations, some proteins form intrachain or interchain disulfide bridges between Cys residues. In eukaryotes, disulfide bonds are common in proteins to be exported from cells. The cross-links formed in this way help to protect the native conformation of the protein molecule from denaturation in the extracellular environment, which can differ greatly from intracellular conditions and is generally oxidizing.

Protein Synthesis Is Inhibited by Many Antibiotics and Toxins

Protein synthesis is a central function in cellular physiology and is the primary target of many naturally occurring antibiotics and toxins. Except as noted otherwise, these antibiotics inhibit protein synthesis in bacteria. The differences between bacterial and eukaryotic protein synthesis, though in some cases subtle, are such that most of the compounds discussed below are relatively harmless to eukaryotic cells. Natural selection has favored the evolution of compounds that exploit minor differences in order to affect bacterial systems selectively, so that these biochemical weapons are synthesized by some microorganisms and are extremely toxic to others. Because nearly every step in protein synthesis can be specifically inhibited by one antibiotic or another, antibiotics have become valuable tools in the study of protein biosynthesis.

Puromycin, made by the mold *Streptomyces alboniger*, is one of the best-understood inhibitory antibiotics. Its structure is very similar to the 3′ end of an aminoacyl-tRNA, enabling it to bind to the ribosomal A site and participate in peptide bond formation, producing peptidylpuromycin (**Fig. 27-36**). Peptidyl puromycin

FIGURE 27-36 Disruption of peptide bond formation by puromycin. The antibiotic puromycin resembles the aminoacyl end of a charged tRNA, and it can bind to the ribosomal A site and participate in peptide bond formation. The product of this reaction, peptidyl puromycin, is not translocated to the P site. Instead, it dissociates from the ribosome, causing premature chain termination.

puromycin resembles only the 3′ end of the tRNA, it does not engage in translocation and dissociates from the ribosome shortly after it is linked to the carboxyl terminus of the peptide. This prematurely terminates polypeptide synthesis.

Tetracyclines inhibit protein synthesis in bacteria by blocking the A site on the ribosome, preventing the binding of aminoacyl-tRNAs. **Chloramphenicol** inhibits protein synthesis by bacterial (and mitochondrial and chloroplast) ribosomes by blocking peptidyl transfer; it does not affect cytosolic protein synthesis in eukaryotes. Conversely, **cycloheximide** blocks the peptidyl transferase of 80S eukaryotic ribosomes but not that of 70S bacterial (and mitochondrial and chloroplast) ribosomes. **Streptomycin**, a basic trisaccharide, causes misreading of the genetic code (in bacteria) at relatively low concentrations and inhibits initiation at higher concentrations.

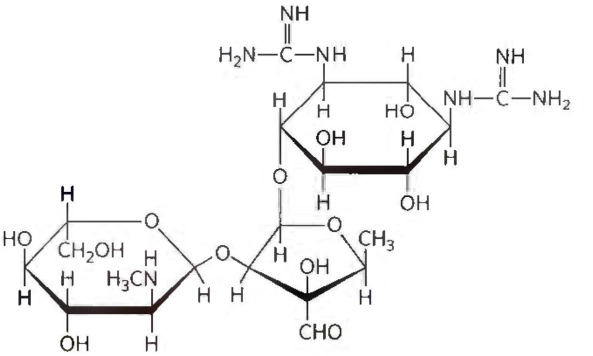
Cycloheximide



Streptomycin

Several other inhibitors of protein synthesis are notable because of their toxicity to humans and other mammals. Diphtheria is a serious bacterial illness that causes sore throat, swollen glands, breathing difficulties, and often death. Although it has been largely eradicated in the developed world, a few thousand cases still occur each year in countries where vaccination is limited. The bacterium *Corynebacterium diphtheriae* releases the **diphtheria toxin** (M_r 58,330), which catalyzes the ADP-ribosylation of a diphthamide (a modified histidine) residue of eukaryotic elongation factor eEF2, thereby inactivating it. The resulting dead cells form a thick, gray membrane that covers the throat and tonsils, creating a putrid odor that is one hallmark of the disease. **Ricin** (M_r 29,895), an extremely toxic protein of the castor bean, inactivates the 60S subunit of eukaryotic ribosomes by depurinating a specific adenosine residue in 28S rRNA. Ricin was used in the infamous 1978 murder of BBC journalist and Bulgarian dissident Georgi Markov, presumably by the Bulgarian secret police. Using a syringe hidden at the end of an umbrella, a member of the secret police injected Markov in the leg with a ricin-infused pellet. He died four days later. ■

SUMMARY 27.2 *Protein Synthesis*

- Protein synthesis occurs on the ribosomes, which consist of protein and rRNA. Bacteria have 70S ribosomes, with a large (50S) and a small (30S) subunit. Eukaryotic ribosomes are significantly larger (80S) and contain more proteins. The growth of polypeptides on ribosomes begins with the amino-terminal amino acid and proceeds by successive additions of new residues to the carboxyl-terminal end.
- Transfer RNAs have 73 to 93 nucleotide residues, some of which have modified bases. Each tRNA has an amino acid arm with the terminal sequence CCA(3′) to which an amino acid is esterified, an anticodon arm, a TψC arm, and a D arm; some tRNAs have a fifth arm. The anticodon is responsible for the specificity of interaction between the aminoacyl-tRNA and the complementary mRNA codon.
- In stage 1 of the five stages of protein synthesis, amino acids are activated by specific aminoacyl-tRNA synthetases in the cytosol. These enzymes catalyze the formation of aminoacyl-tRNAs, with simultaneous cleavage of ATP to AMP and PP_i. The fidelity of protein synthesis depends on the accuracy of this reaction, and some of these enzymes carry out proofreading steps at separate active sites.
- Stage 2 is initiation. In bacteria, the initiating aminoacyl-tRNA in all proteins is *N*-formylmethionyl-$\text{tRNA}^{\text{fMet}}$. Initiation of protein synthesis involves formation of a complex between the 30S ribosomal subunit, mRNA, GTP, fMet-$\text{tRNA}^{\text{fMet}}$, three initiation factors, and the 50S subunit; GTP is hydrolyzed to GDP and P_i.
- Stage 3 is elongation. In the elongation steps, GTP and elongation factors are required for binding the incoming aminoacyl-tRNA to the A site on the ribosome. In the first peptidyl transfer reaction, the fMet residue is transferred to the amino group of the incoming aminoacyl-tRNA. Movement of the ribosome along the mRNA then translocates the dipeptidyl-tRNA from the A site to the P site, a process requiring hydrolysis of GTP. Deacylated tRNAs dissociate from the ribosomal E site.
- Stage 4 is termination. After many such elongation cycles, synthesis of the polypeptide is terminated with

the aid of release factors. At least four high-energy phosphate equivalents (from ATP and GTP) are required to generate each peptide bond, an energy investment required to guarantee fidelity of translation.

- Stage 5 is protein processing. Polypeptides fold into their active, three-dimensional forms. Many proteins are further processed by posttranslational modification reactions.
- Many well-studied antibiotics and toxins inhibit some aspect of protein synthesis.

27.3 Protein Targeting and Degradation

The eukaryotic cell is made up of many structures, compartments, and organelles, each with specific functions that require distinct sets of proteins and enzymes. These proteins (with the exception of those produced in mitochondria and plastids) are synthesized on ribosomes in the cytosol, so how are they directed to their final cellular destinations?

We are now beginning to understand this complex and fascinating process. Proteins destined for secretion, integration in the plasma membrane, or inclusion in lysosomes generally share the first few steps of a pathway that begins in the endoplasmic reticulum. Proteins destined for mitochondria, chloroplasts, or the nucleus use three separate mechanisms. And proteins destined for the cytosol simply remain where they are synthesized. **P1** The thermodynamic cost of protein synthesis is magnified by the processes used by cells to transport proteins to their correct cellular locations.

The most important element in many of these targeting pathways is a short sequence of amino acids called a **signal sequence**, whose function was first postulated by Günter Blobel and colleagues in 1970. The signal sequence directs a protein to its appropriate location in the cell and, for many proteins, is removed during transport or after the protein has reached its final destination. In proteins slated for transport into mitochondria, chloroplasts, or the ER, the signal sequence is at the amino terminus of a newly synthesized polypeptide. In many cases, the targeting capacity of particular signal sequences has been confirmed by fusing the signal sequence from one protein to a second protein and showing that the signal directs the second protein to the location where the first protein is normally found. The selective degradation of proteins no longer needed by the cell also relies largely on a set of molecular signals embedded in each protein's structure.

In this concluding section we examine protein targeting and degradation, emphasizing the underlying signals and molecular regulation that are so crucial to cellular metabolism. Except where noted, the focus is now on eukaryotic cells.

Posttranslational Modification of Many Eukaryotic Proteins Begins in the Endoplasmic Reticulum

Perhaps the best-characterized targeting system begins in the ER. Most lysosomal, membrane, or secreted proteins have an amino-terminal signal sequence (**Fig. 27-37**) that marks them for translocation into the lumen of the ER; hundreds of such signal sequences have been determined. The carboxyl terminus of the signal sequence is defined by a cleavage site, where protease action removes the sequence after the protein is imported into the ER. Signal sequences vary in length from 13 to 36 amino acid residues, but all have the following features: (1) about 10 to 15 hydrophobic amino acid residues; (2) one or more positively charged residues, usually near the amino terminus, preceding the hydrophobic sequence; and (3) a short sequence at the carboxyl terminus (near the cleavage site) that is relatively polar, typically having amino acid residues with short side chains (especially Ala) at the positions closest to the cleavage site.

As originally demonstrated by the cell biologist George Palade, proteins with these signal sequences are synthesized on ribosomes attached to the ER. The signal sequence itself helps to direct the ribosome to the ER, as illustrated in **Figure 27-38**. The targeting pathway begins in step ①, with initiation of protein synthesis on

Polar and short-side-chain residues immediately precede (to the left, as shown here) the cleavage sites (indicated by red arrows).

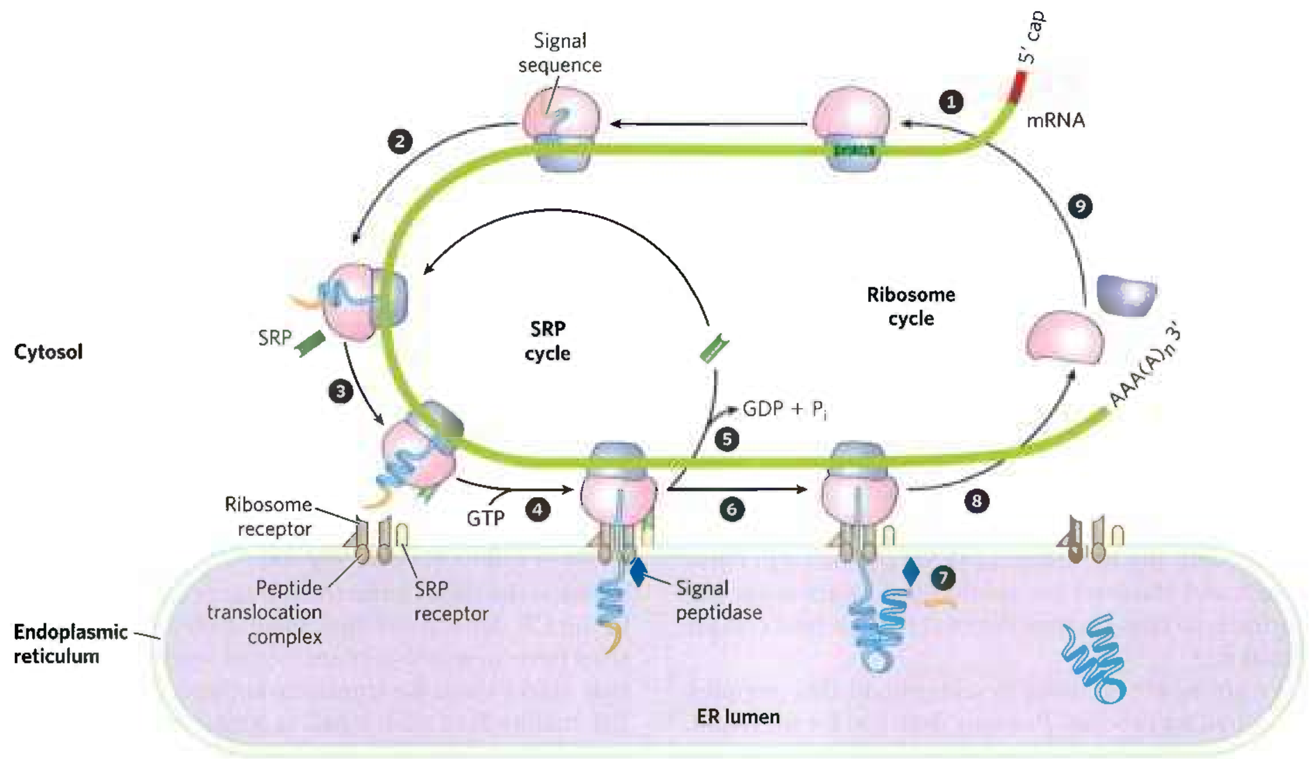

FIGURE 27-38 Directing eukaryotic proteins with the appropriate signals to the endoplasmic reticulum. This process involves the SRP cycle and the translocation and cleavage of the nascent polypeptide. One protein subunit of SRP binds directly to the signal sequence, obstructing elongation by sterically blocking the entry of aminoacyl-tRNAs and inhibiting peptidyl transferase. Another protein subunit binds and hydrolyzes GTP.

free ribosomes. The signal sequence appears early in the synthetic process (step ②), because it is at the amino terminus, which, as we have seen, is synthesized first. As it emerges from the ribosome (step ③), the signal sequence—and the ribosome itself—is bound by the large **signal recognition particle (SRP)**. The SRP is a rod-shaped complex containing a 300 nucleotide RNA (7SL-RNA) and six different proteins (combined M_r 325,000). The SRP then binds GTP and halts elongation of the polypeptide when it is about 70 amino acids long and the signal sequence has completely emerged from the ribosome. In step ④, the GTP-bound SRP directs the ribosome (still bound to the mRNA) and the incomplete polypeptide to GTP-bound SRP receptors in the cytosolic face of the ER; the nascent polypeptide is delivered to a **peptide translocation complex** in the ER, which interacts directly with the ribosome. In step ⑤, the SRP dissociates from the ribosome, accompanied by hydrolysis of GTP in both the SRP and the SRP receptor. The SRP receptor is a heterodimer of α (M_r 69,000) and β (M_r 30,000) subunits, both of which bind and hydrolyze multiple GTP molecules during this process.

Elongation of the polypeptide now resumes (step ⑥), with the ATP-driven translocation complex feeding the growing polypeptide into the ER lumen until the complete protein has been synthesized. In step ⑦, the signal sequence is removed by a signal peptidase within the ER lumen. The ribosome dissociates (step ⑧) and is recycled (step ⑨).

Glycosylation Plays a Key Role in Protein Targeting

In the ER lumen, newly synthesized proteins are further modified in several ways. Following the removal of signal sequences, polypeptides are folded, disulfide bonds are formed, and many proteins are glycosylated to form glycoproteins. In many glycoproteins, the linkage to their oligosaccharides is through Asn residues. These *N*-linked oligosaccharides are diverse (Chapter 7), but the pathways by which they form have a common first step. A 14 residue core oligosaccharide is built up stepwise, first on the cytosolic face of the membrane and then on the lumenal face. Once completed, it is transferred from a dolichol phosphate donor molecule to certain Asn residues in the protein (Fig. 27-39). The transferase is on the lumenal face of the ER and thus cannot catalyze glycosylation of cytosolic proteins. After transfer, the core oligosaccharide is trimmed and elaborated in different ways on different proteins, but all *N*-linked oligosaccharides retain a pentasaccharide core derived from the original 14 residue oligosaccharide.

Several antibiotics act by interfering with one or more steps in this process and have aided in elucidating the steps of protein glycosylation. The best characterized is **tunicamycin**, which mimics the structure of UDP-*N*-acetylglucosamine and blocks the first step of the process (Fig. 27-39, step ①). A few proteins are *O*-glycosylated in the ER, but most *O*-glycosylation occurs in the Golgi complex or in the cytosol (for proteins that do not enter the ER).

FIGURE 27-39 Synthesis of the core oligosaccharide of glycoproteins. The core oligosaccharide is built up by the successive addition of monosaccharide units. ①, ② The first steps occur on the cytosolic face of the ER. ③ Translocation moves the incomplete oligosaccharide across the membrane (mechanism not shown), and ④ completion of the core oligosaccharide occurs within the lumen of the ER. The precursors that contribute additional mannose and glucose residues to the growing oligosaccharide in the lumen are dolichol phosphate derivatives. ⑤ In the first step in construction of the *N*-linked oligosaccharide moiety of a glycoprotein, the core oligosaccharide is transferred from dolichol phosphate to an Asn residue of the protein, and ⑥ protein synthesis continues. The core oligosaccharide is then further modified in the ER and the Golgi complex in pathways that differ for different proteins. The five sugar residues shown surrounded by a beige screen, after step ⑦, are retained in the final structure of all *N*-linked oligosaccharides. ⑧ The released dolichol pyrophosphate is again translocated so that the pyrophosphate is on the cytosolic face of the ER, then ⑨ a phosphate is hydrolytically removed to regenerate dolichol phosphate.

Suitably modified proteins can now be moved to a variety of intracellular destinations. Proteins travel from the ER to the Golgi complex in transport vesicles (**Fig. 27-40**). In the Golgi complex, oligosaccharides are *O*-linked to some proteins, and *N*-linked oligosaccharides are further modified. By mechanisms not yet fully understood, the Golgi complex also sorts proteins and sends them to their final destinations. The processes that segregate proteins targeted for secretion from those targeted for the plasma membrane or lysosomes must distinguish among these proteins on the basis of structural features other than signal sequences, which were removed in the ER lumen.

This sorting process is best understood in the case of hydrolases destined for transport to lysosomes. On arrival of a hydrolase (a glycoprotein) in the Golgi complex, an as yet undetermined feature (sometimes called a signal patch) of the three-dimensional structure of the hydrolase is recognized by a phosphotransferase, which phosphorylates terminal mannose residues in the oligosaccharides (**Fig. 27-41**). The presence of one or more mannose 6-phosphate residues in its *N*-linked

oligosaccharide is the structural signal that targets a protein to lysosomes. A receptor protein in the membrane of the Golgi complex recognizes the mannose 6-phosphate signal and binds the hydrolase so marked. Vesicles containing these receptor-hydrolase complexes bud from the trans side of the Golgi complex and make their way to sorting vesicles. Here, the receptor-hydrolase complex dissociates in a process facilitated by the lower pH in the vesicle and by phosphatase-catalyzed removal of phosphate groups from the mannose 6-phosphate residues. The receptor is then recycled to the Golgi complex, and vesicles containing the hydrolases bud from the sorting vesicles and move to the lysosomes. In cells treated with tunicamycin (Fig. 27-39, step ①), hydrolases that should be targeted to lysosomes are instead secreted, confirming that the *N*-linked oligosaccharide plays a key role in targeting these enzymes to lysosomes.

The pathways that target proteins to mitochondria and chloroplasts also rely on amino-terminal signal sequences. Although mitochondria and chloroplasts contain DNA,

most of their proteins are encoded by nuclear DNA and must be targeted to the appropriate organelle. Unlike other targeting pathways, however, the mitochondrial and chloroplast pathways begin only *after* a precursor protein has been completely synthesized and released from the ribosome. Precursor proteins destined for mitochondria or chloroplasts are bound by cytosolic chaperone proteins and delivered to receptors on the exterior surface of the target organelle. Specialized translocation mechanisms then transport the protein to its final destination in the organelle, after which the signal sequence is removed.

Signal Sequences for Nuclear Transport Are Not Cleaved

Molecular communication between the nucleus and the cytosol requires the movement of macromolecules through nuclear pores. RNA molecules synthesized in the nucleus are exported to the cytosol. Ribosomal proteins synthesized on cytosolic ribosomes are imported into the nucleus and assembled into 60S and 40S ribosomal subunits in the nucleolus; completed subunits are then exported back to the cytosol (Fig. 27-17). A variety of nuclear proteins (RNA and DNA polymerases, histones, topoisomerases, proteins that regulate gene expression, and so forth) are synthesized in the cytosol and imported into the nucleus. This traffic is modulated by a complex system of molecular signals and transport proteins that is gradually being elucidated.

In most multicellular eukaryotes, the nuclear envelope breaks down at each cell division, and once division is completed and the nuclear envelope reestablished, the dispersed nuclear proteins must be reimported. To allow this repeated nuclear importation, the signal sequence that targets a protein to the nucleus—the **nuclear localization sequence (NLS)**—is not removed after the protein arrives at its destination. An NLS, unlike other signal sequences, may be located almost anywhere along the primary sequence of the protein. NLSs can vary considerably in structure, but many consist of four to eight amino acid residues and include several consecutive basic (Arg or Lys) residues.

Nuclear importation is mediated by several proteins that cycle between the cytosol and the nucleus (Fig. 27-42),

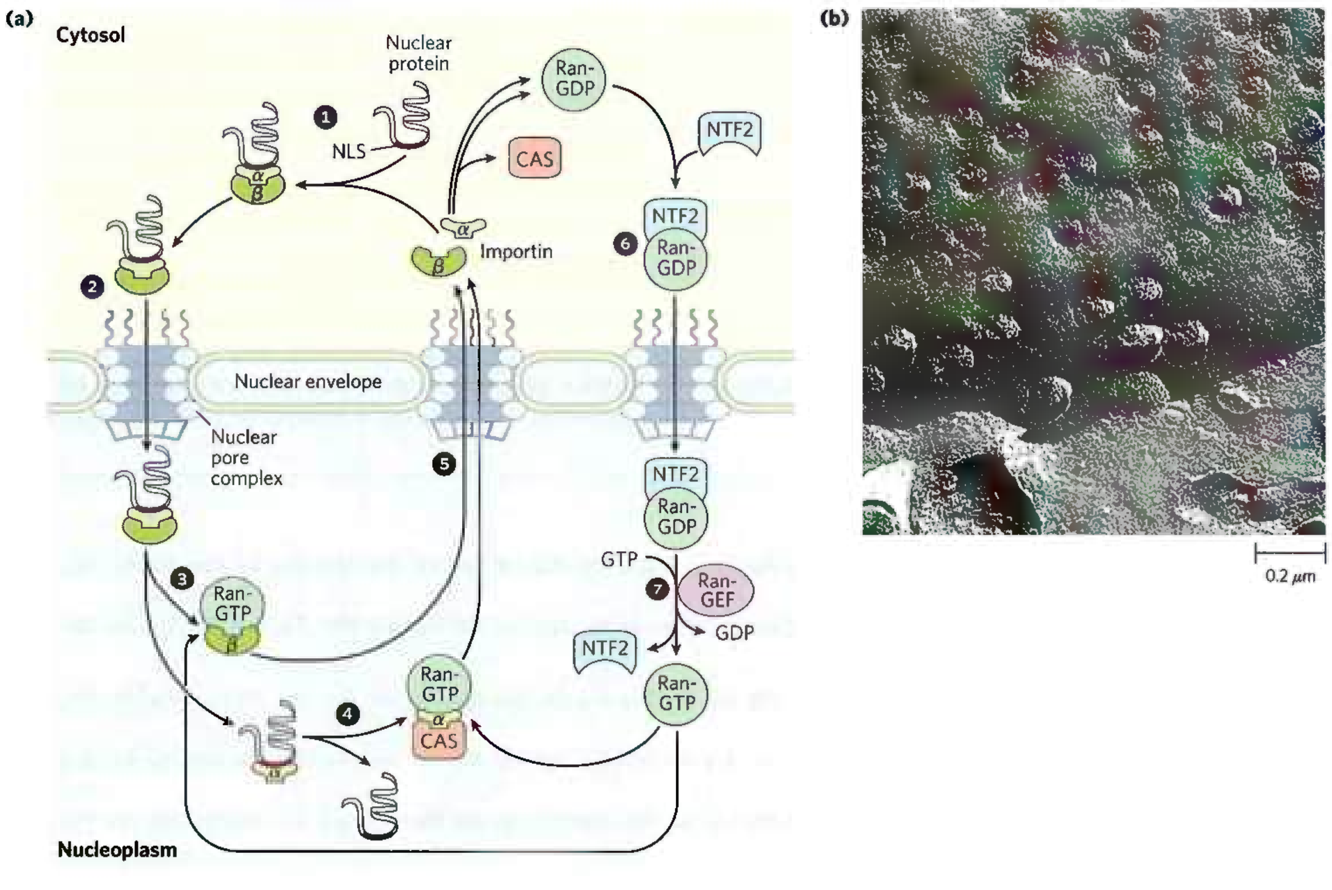

FIGURE 27-42 Targeting of nuclear proteins. (a) ① A protein with an appropriate nuclear localization signal (NLS) is bound by a complex of importins α and β. ② The resulting complex binds to a nuclear pore and translocates. ③ Inside the nucleus, dissociation of importin β is promoted by the binding of Ran-GTP. ④ Importin α binds to Ran-GTP and CAS (cellular apoptosis susceptibility protein), releasing the nuclear protein. ⑤ Importins α and β and CAS are transported out of the nucleus and recycled. They are released in the cytosol when Ran hydrolyzes its bound GTP. ⑥ Ran-GDP is bound by NTF2, and transported back into the nucleus. ⑦ Ran-GEF promotes the exchange of GDP for GTP in the nucleus, and Ran-GTP is ready to process another NLS-bearing protein-importin complex. (b) Transmission electron micrograph of a freeze-fractured nucleus, showing numerous nuclear pores. The nuclear pore complex is one of the largest molecular aggregates in the cell (M_r ~5×10^7). It is made up of multiple copies of more than 30 different proteins. [(a) Information from C. Strambio-De-Castillia et al., *Nat. Rev. Mol. Cell Biol.* 11:490, 2010, Fig. 1. (b) Don W. Fawcett/Science Source.]

including importin α and β and a small GTPase known as Ran (*Ra*s-related *n*uclear protein). A heterodimer of importin α and β functions as a soluble receptor for proteins targeted to the nucleus, with the α subunit binding NLS-bearing proteins in the cytosol. The complex of the NLS-bearing protein and the importin docks at a nuclear pore and is translocated through the pore by an energy-dependent mechanism. In the nucleus, the importin β is bound by Ran GTPase, releasing importin β from the imported protein. Importin β is bound by Ran and by CAS (*c*ellular *a*poptosis *s*usceptibility protein) and separated from the NLS-bearing protein. Importin α and β, in their complexes with Ran and CAS, are then exported from the nucleus. Ran hydrolyzes GTP in the cytosol to release the importins, which are then free to begin another importation cycle. Ran itself is also cycled back into the nucleus by the binding of Ran-GDP to nuclear transport factor 2 (NTF2). Inside the nucleus, the GDP bound to Ran is replaced with GTP through the action of Ran guanosine nucleotide–exchange factor (Ran-GEF).

During mitosis, when the nuclear envelope transiently breaks down, the Ran GTPase and the importins play additional roles. The Ran GTPase–importin β complex helps to position the spindle microtubules on the cell perimeter to facilitate chromosome segregation as the cell divides, and this complex also regulates microtubule interaction with other cellular structures.

Bacteria Also Use Signal Sequences for Protein Targeting

Bacteria can target proteins to their inner or outer membranes, to the periplasmic space between these membranes, or to the extracellular medium. They use signal sequences at the amino terminus of the proteins (**Fig. 27-43**), much like those on eukaryotic proteins targeted to the ER, mitochondria, and chloroplasts.

Most proteins exported from *E. coli* make use of the pathway shown in **Figure 27-44**. Following translation, a protein to be exported may fold only slowly, the amino-terminal signal sequence impeding the folding. The soluble chaperone protein SecB binds to the protein's signal sequence or other features of its incompletely folded structure. The bound protein is then delivered to SecA, a protein associated with the inner surface of the plasma membrane. SecA acts as both a receptor and a translocating ATPase. Released from SecB and bound to SecA, the protein is delivered to a translocation complex in the membrane, made up of SecY, E, and G, and is translocated stepwise through the membrane at the SecYEG complex in lengths of about 20 amino acid residues. Each step requires the hydrolysis of ATP, catalyzed by SecA.

Although most exported bacterial proteins use this pathway, some follow an alternative pathway that uses signal recognition and receptor proteins homologous to components of the eukaryotic SRP and the SRP receptor (see Fig. 27-38).

Cells Import Proteins by Receptor-Mediated Endocytosis

Some proteins are imported into eukaryotic cells from the surrounding medium; examples include low-density lipoprotein (LDL), the iron-carrying protein transferrin, peptide hormones, and circulating proteins destined for degradation. There are several importation pathways (**Fig. 27-45**). In one path, proteins bind to receptors in invaginations of the membrane called **coated pits**, which concentrate endocytic receptors in preference to other cell-surface proteins. The pits are coated on their cytosolic side with a lattice of the protein **clathrin**, which forms closed polyhedral structures (**Fig. 27-46**). The clathrin lattice grows as more receptors are occupied by target proteins. Eventually, a complete membrane-bounded

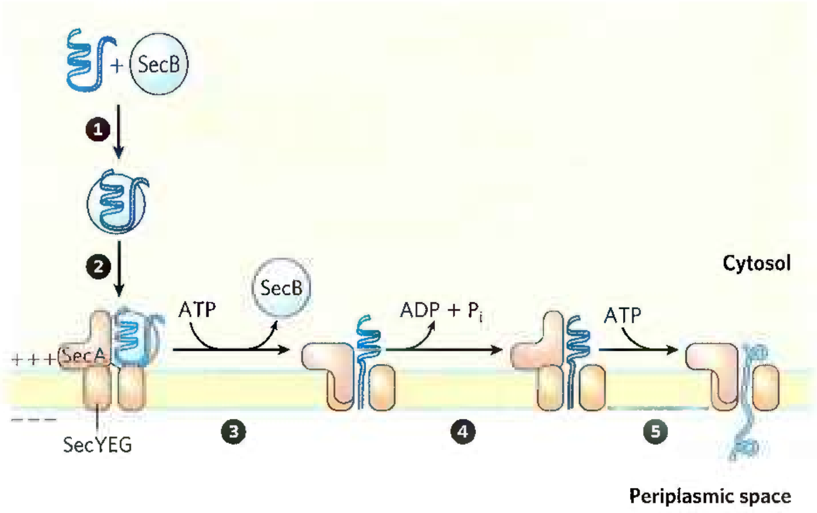

FIGURE 27-44 Model for protein export in bacteria. ① A newly translated polypeptide binds to the cytosolic chaperone protein SecB, which ② delivers it to SecA, a protein associated with the translocation complex (SecYEG) in the bacterial cell membrane. ③ SecB is released, and SecA inserts itself into the membrane, forcing about 20 amino acid residues of the protein to be exported through the translocation complex. ④ Hydrolysis of an ATP by SecA provides the energy for a conformational change that causes SecA to withdraw from the membrane, releasing the polypeptide. ⑤ SecA binds another ATP, and the next stretch of 20 amino acid residues is pushed across the membrane through the translocation complex. Steps ④ and ⑤ are repeated until the entire protein has passed through and is released to the periplasm. The electrochemical potential across the membrane (denoted by + and −) also provides some of the driving force required for protein translocation.

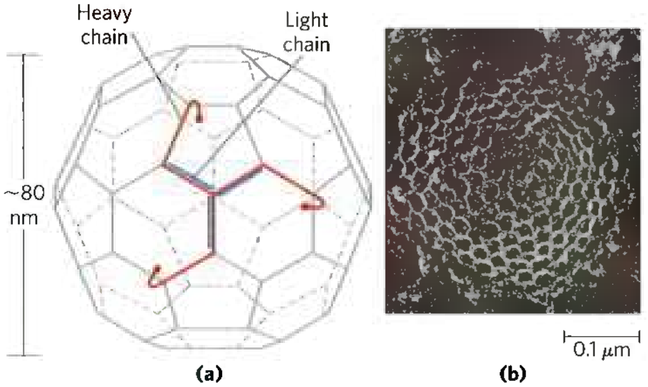
FIGURE 27-45 Summary of endocytosis pathways in eukaryotic cells. Pathways dependent on clathrin or caveolin make use of the GTPase dynamin to pinch vesicles from the plasma membrane. Some pathways do not use clathrin or caveolin; some of these make use of dynamin and some do not.



(a) (b)

FIGURE 27-46 Clathrin. (a) The protein has three light (L) chains (M_r 35,000) and three heavy (H) chains (M_r 180,000) of the $(HL)_3$ clathrin unit, organized as a three-legged structure called a triskelion. Triskelions tend to assemble into polyhedral lattices. (b) Electron micrograph of a coated pit on the cytosolic face of the plasma membrane of a fibroblast. [(a) Information from S. Mayor and R. E. Pagano, *Nat. Rev. Mol. Cell Biol.* 8:603, 2007. (b) ©1980 Heuser. The Rockefeller University Press. J. Heuser, *J. Cell Biol.* 84:560, 1980.]

endocytic vesicle is pinched off the plasma membrane with the aid of the large GTPase **dynamin**, and it enters the cytoplasm. The clathrin is quickly removed by uncoating enzymes, and the vesicle fuses with an endosome. ATPase activity in the endosomal membranes reduces the pH therein, facilitating dissociation of receptors from their target proteins. In a related pathway, caveolin causes invagination of patches of membrane containing lipid rafts associated with certain types of receptors (see Fig. 11-23). These endocytic vesicles then fuse with caveolin-containing internal structures called caveosomes, where the internalized molecules are sorted and redirected to other parts of the cell and the caveolins are prepared for recycling to the membrane surface. There are also clathrin- and caveolin-independent pathways; some make use of dynamin and others do not.

The imported proteins and receptors then go their separate ways, their fates varying with the cell and protein type. Transferrin and its receptor are eventually recycled. Some hormones, growth factors, and immune complexes, after eliciting the appropriate cellular response, are degraded along with their receptors. LDL is degraded after the associated cholesterol has been delivered to its destination, but the LDL receptor is recycled (see Fig. 21-42).

Receptor-mediated endocytosis is exploited by some toxins and viruses to gain entry to cells. Influenza virus, diphtheria toxin, SARS-CoV-2 (the virus that causes COVID-19), and cholera toxin all enter cells in this way.

Protein Degradation Is Mediated by Specialized Systems in All Cells

Protein degradation is critical to overall cellular proteostasis, preventing the buildup of abnormal or unwanted proteins and permitting the recycling of amino acids. The half-lives of eukaryotic proteins vary from 30 seconds to many days. Most proteins turn over rapidly relative to the lifetime of a cell, although a few (such as hemoglobin) can last for the life of the cell (about 110 days for an erythrocyte). Rapidly degraded proteins include those that are defective because of incorrectly inserted amino acids or because of damage accumulated during normal functioning. And enzymes that act at key regulatory points in metabolic pathways often turn over rapidly.

Defective proteins and those with characteristically short half-lives are generally degraded in both bacterial and eukaryotic cells by selective ATP-dependent cytosolic systems. A second system in vertebrates, operating in lysosomes, recycles the amino acids of membrane proteins, extracellular proteins, and proteins with characteristically long half-lives.

In *E. coli*, many proteins are degraded by one of several proteolytic systems that contain AAA+ ATPases (see Chapter 25), including Lon (the name refers to the "long form" of proteins, observed only when this protease is absent), ClpXP, ClpAP, ClpCP, ClpYQ, and FtsH. Each system targets particular proteins distinguished by their structure or subcellular location or both. Typically, ATP hydrolysis is used to maneuver a target protein through a pore into a proteolytic chamber, unfolding the protein in the process. Proteins are cleaved within the chamber. Once a protein has been reduced to small, inactive peptides, other ATP-independent proteases complete their degradation.

The ATP-dependent pathway in eukaryotic cells is quite different, involving the protein **ubiquitin**, which, as its name suggests, occurs throughout the eukaryotic kingdoms. One of the most highly conserved proteins known, ubiquitin (76 amino acid residues) is essentially identical in organisms as different as yeasts and humans and is key to proteostasis (see Figs. 4-23 and 13-29) and cell cycle regulation (see Fig. 12-38). Ubiquitin is covalently linked to proteins slated for destruction via an ATP-dependent pathway that includes three separate types of enzymes: E1 activating enzymes, E2 conjugating enzymes, and E3 ligases (**Fig. 27-47**).

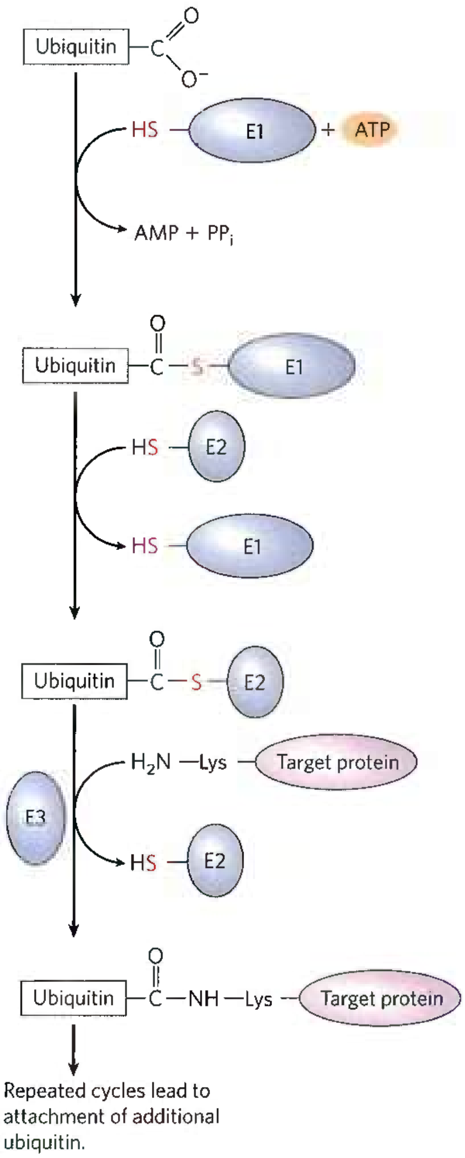


FIGURE 27-47 Three-step pathway by which ubiquitin is attached to a protein. The pathway includes two different enzyme-ubiquitin intermediates. First, the free carboxyl group of ubiquitin's carboxyl-terminal Gly residue becomes linked to an E1-class activating enzyme through a thioester. The ubiquitin is then transferred to an E2 conjugating enzyme. An E3 ligase ultimately catalyzes transfer of the ubiquitin from E2 to the target, linking ubiquitin through an amide (isopeptide) bond to the ε-amino group of a Lys residue in the target protein. Additional cycles produce polyubiquitin, a covalent polymer of ubiquitin subunits that targets the attached protein for destruction in eukaryotes. Multiple pathways of this sort, with different protein targets, are present in most eukaryotic cells.

Ubiquitinated proteins are degraded by a large complex known as the **26S proteasome** (M_r 2.5×10^6) (**Fig. 27-48**). The eukaryotic proteasome consists of two copies each of at least 32 different subunits, most of which are highly conserved from yeasts to humans. The proteasome contains two main types of subcomplexes: a barrel-like core particle and regulatory particles at each end of the barrel. The 19S regulatory particle on each end of the core particle contains approximately 18 subunits,

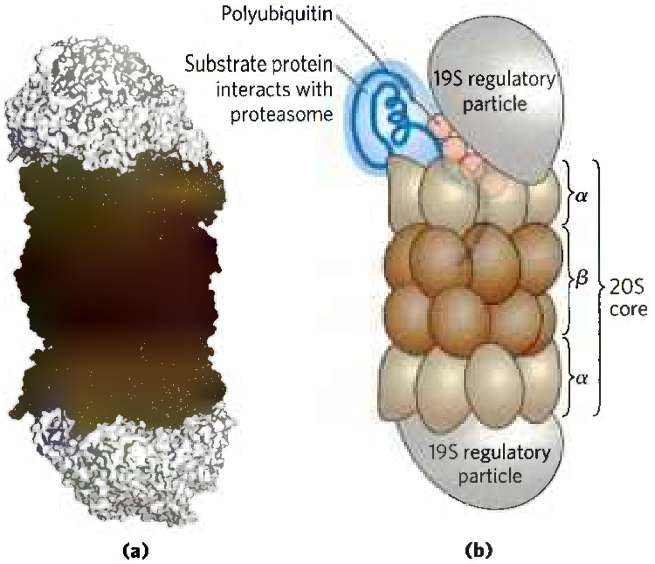

FIGURE 27-48 Three-dimensional structure of the eukaryotic proteasome. The 20S core particle and the 19S regulatory particle, or cap, are shown (a) as a molecular structure and (b) in schematic form. The core particle consists of four rings arranged to form a barrel-like structure. The outer rings are formed from seven α subunits, and the inner rings from seven β subunits. Three of the β subunits have protease activities, each with different substrate specificity. A regulatory particle forms a cap on each end of the core particle. The regulatory particle binds ubiquitinated proteins, unfolds them, and translocates them into the core particle, where they are degraded to peptides of 3 to 25 amino acid residues. [(a) Data from PDB ID 3L5Q, K. Sadre-Bazzaz et al., *Mol. Cell* 37:728, 2010.]

Pro	~7 min
Asp, Leu, Lys, Phe	~3 min
Arg	~2 min

Information from A. Bachmair et al., *Science* 234:179, 1986.

[a] Half-lives were measured in yeast for the β-galactosidase protein modified so that in each experiment it had a different amino-terminal residue. Half-lives may vary for different proteins and in different organisms, but this general pattern appears to hold for all organisms.

including some that recognize and bind to ubiquitinated proteins. Six of the subunits are AAA+ ATPases that probably function in unfolding the ubiquitinated proteins and translocating the unfolded polypeptide into the core particle for degradation. The 19S particle also deubiquitinates the proteins as they are degraded in the proteasome. Most cells have additional regulatory complexes that can replace the 19S particle. These alternative regulators do not hydrolyze ATP and do not bind to ubiquitin, but they are important for the degradation of particular cellular proteins. The 26S proteasome can be effectively "accessorized" with regulatory complexes that change with changing cellular conditions.

Although we do not yet understand all the signals that trigger ubiquitination, one simple signal has been found. For many proteins, the identity of the first residue that remains after removal of the amino-terminal Met residue, and any other posttranslational proteolytic processing of the amino-terminal end, has a profound influence on half-life (**Table 27-9**). These amino-terminal signals have been conserved over billions of years of evolution and are the same in bacterial protein degradation systems and in the human ubiquitination pathway. More complex signals, such as the destruction box discussed in Chapter 12 (see Fig. 12-38), are also being identified.

Ubiquitin-dependent proteolysis is as important for the regulation of cellular processes as it is for the elimination of defective proteins. Many proteins required at only one stage of the eukaryotic cell cycle are rapidly degraded by the ubiquitin-dependent pathway after fulfilling their function. Ubiquitin-dependent destruction of cyclin is critical to cell-cycle regulation. The E1, E2, and E3 components of the ubiquitination pathway (Fig. 27-47) are large families of proteins. Different E1, E2, and E3 enzymes exhibit different specificities for target proteins and thus regulate different cellular processes. Some of these enzymes are highly localized in certain cellular compartments, reflecting a specialized function.

Not surprisingly, defects in the ubiquitination pathway have been implicated in a wide range of disease states. An inability to degrade certain proteins that activate cell division (the products of oncogenes) can lead to tumor formation, and a too-rapid degradation of proteins that act as tumor suppressors can have the same effect. The ineffective or overly rapid degradation of cellular proteins also seems to play a role in a range of other conditions, including renal diseases, asthma, and neurodegenerative disorders such as Alzheimer and Parkinson diseases that are associated with the formation of characteristic proteinaceous structures in neurons. Cystic fibrosis is caused in some cases by a too-rapid degradation of a chloride ion channel, with resultant loss of function (see Box 11-2). Liddle syndrome, in which a sodium channel in the kidney is not degraded, leads to excessive Na^+ absorption and early-onset hypertension. Drugs designed to inhibit proteasome function are being developed as potential treatments for some of these conditions. Many bacterial pathogens have found ways to hijack the eukaryotic ubiquitination system, evolving enzymes that ubiquitinate and thus eliminate host proteins as required to facilitate infection. In a changing metabolic environment, protein degradation is as important to a cell's survival as is protein synthesis, and much remains to be learned about these interesting pathways. ■

SUMMARY 27.3 *Protein Targeting and Degradation*

- After synthesis, many proteins are directed to particular locations in the cell, a process mediated by signal sequences embedded in the polypeptide chain. In eukaryotic cells, one class of signal sequences is recognized by the signal recognition particle (SRP), which binds the signal sequence as soon as it appears on the ribosome and transfers the entire ribosome and incomplete polypeptide to the endoplasmic reticulum. Polypeptides with these signal sequences are moved into the endoplasmic reticulum lumen as they are synthesized.
- Once in the lumen of the ER, many proteins are glycosylated. So modified, they are moved to the Golgi complex, then sorted and sent to lysosomes, the plasma membrane, or transport vesicles.
- Proteins targeted to the nucleus have an internal signal sequence that, unlike other signal sequences, is not cleaved once the protein is successfully targeted.
- Proteins targeted to mitochondria and chloroplasts in eukaryotic cells, and those destined for export in bacteria, also make use of an amino-terminal signal sequence.
- Some eukaryotic cells import proteins by receptor-mediated endocytosis.
- All cells eventually degrade proteins, using specialized proteolytic systems. Defective proteins and those slated for rapid turnover are generally degraded by an ATP-dependent system. In eukaryotic cells, the proteins are first tagged by linkage to ubiquitin, a highly conserved protein. Ubiquitin-dependent proteolysis, critical to the regulation of many cellular processes, is carried out by proteasomes, which also are highly conserved.

KEY TERMS

Terms in bold are defined in the glossary.

proteostasis	1005
translation	1006
aminoacyl-tRNA	1006
aminoacyl-tRNA synthetases	1006
codon	1007
reading frame	1007
initiation codon	1009
termination codons	1009
open reading frame (ORF)	1009
degenerate code	1009
anticodon	1010
wobble	1012
translational frameshifting	1013
RNA editing	1013
initiation	1028
Shine-Dalgarno sequence	1028
aminoacyl (A) site	1028
peptidyl (P) site	1028
exit (E) site	1028
initiation complex	1028
elongation	1030
elongation factors	1030
peptidyl transferase	1032
translocation	1032
termination	1035
termination factors	1035
release factors	1035
polysome	1036
posttranslational modification	1037
puromycin	1039
tetracycline	1040
chloramphenicol	1040
cycloheximide	1040
streptomycin	1040
diphtheria toxin	1040
ricin	1040
signal sequence	1041
signal recognition particle (SRP)	1042
peptide translocation complex	1042
tunicamycin	1042
nuclear localization sequence (NLS)	1045
coated pits	1046
clathrin	1046
dynamin	1047
ubiquitin	1048
proteasome	1048

PROBLEMS

1. **Messenger RNA Translation** Predict the amino acid sequences of peptides formed by ribosomes in response to each mRNA sequence, assuming that the reading frame begins with the first three bases in each sequence.

(a) GGUCAGUCGCUCCUGAUU
(b) UUGGAUGCGCCAUAAUUUGCU
(c) CAUGAUGCCUGUUGCUAC
(d) AUGGACGAA

2. **How Many Different mRNA Sequences Can Specify One Amino Acid Sequence?** Write all the possible mRNA sequences that can code for the simple tripeptide segment Leu–Met–Tyr. Your answer will give you some idea of the number of possible mRNAs that can code for one polypeptide.

3. **Can the Base Sequence of an mRNA Be Predicted from the Amino Acid Sequence of Its Polypeptide Product?** A given sequence of bases in an mRNA will code for one and only one sequence of amino acids in a polypeptide, if the reading frame is specified. From a given sequence of amino acid residues in a protein such as cytochrome *c*, can we predict the base sequence of the unique mRNA that encoded it? Give reasons for your answer.

4. **Coding of a Polypeptide by Duplex DNA** The template strand of a segment of double-helical DNA contains the sequence

(5′)CTTAACACCCCTGACTTCGCGCCGTCG(3′)

(a) What is the base sequence of the mRNA that can be transcribed from this strand?
(b) What amino acid sequence could be coded by the mRNA in (a), starting from the 5′ end?
(c) If the complementary (nontemplate) strand of this DNA were transcribed and translated, would the resulting amino acid sequence be the same as in (b)? Explain the biological significance of your answer.

5. **The Genetic Code and Mutation** A mutation occasionally arises that converts a codon specifying an amino acid to a stop or nonsense codon. When this occurs in the middle of a gene, the resulting protein is truncated and often inactive. If the protein is essential, cell death can result. Which of these secondary mutations might restore some or all of the protein function so that the cell can survive (there may be more than one correct answer)?

(a) A mutation restoring the codon to one encoding the original amino acid
(b) A mutation changing the nonsense codon to one encoding a different but similar amino acid

(c) A mutation in the anticodon of a tRNA such that the tRNA now recognizes the nonsense codon

(d) A mutation in which an additional nucleotide inserts just upstream of the nonsense codon, changing the reading frame so the nonsense codon is no longer read as "stop"

6. The Direction of Protein Synthesis In 1961, Howard Dintzis established that protein synthesis on ribosomes begins at the amino terminus and proceeds toward the carboxyl terminus. He used immature red blood cells that were still synthesizing hemoglobin. He added radioactively labeled leucine (chosen because it occurs frequently in both the α and β subunits) for various lengths of time, rapidly isolated only the full-length (completed) α subunits, and then determined where in the peptide the labeled amino acids were located. After the labeled leucine and extract had been incubated together for one hour, the protein was labeled uniformly along its length. However, after much shorter incubation times, the labeled amino acids were clustered at one end. At which end, amino or carboxyl terminus, did Dintzis find the labeled residues after the short exposure to labeled leucine?

7. Methionine Has Only One Codon Methionine is one of two amino acids with only one codon. How does the single codon for methionine specify both the initiating residue and the interior Met residues of polypeptides synthesized by *E. coli*?

8. The Genetic Code in Action Translate the mRNA shown, starting at the first 5′ nucleotide, assuming that translation occurs in an *E. coli* cell. If all tRNAs make maximum use of wobble rules but do not contain inosine, how many distinct tRNAs are required to translate this RNA?

(5′)AUGGGUCGUGAGUCAUCGUUAAUUGUAGCUGGAGGGGA GGAAUGA(3′)

9. Synthetic mRNAs The genetic code was elucidated through the use of polyribonucleotides synthesized either enzymatically or chemically in the laboratory. Given what we now know about the genetic code, how would you make a polyribonucleotide that could serve as an mRNA coding predominantly for many Phe residues and for a small number of Leu and Ser residues? What other amino acid(s) would be encoded by this polyribonucleotide, but in smaller amounts?

10. Energy Cost of Protein Biosynthesis Determine the minimum energy cost, in terms of ATP equivalents expended, for the biosynthesis of the β-globin chain of hemoglobin (146 residues), starting from a pool including all necessary amino acids, ATP, and GTP. Compare your answer with the direct energy cost of the biosynthesis of a linear glycogen chain of 146 glucose residues in ($\alpha 1 \rightarrow 4$) linkage, starting from a pool including glucose, UTP, and ATP. From your data, what is the *extra* energy cost of making a protein, in which all the residues are ordered in a specific sequence, compared with the cost of making a polysaccharide containing the same number of residues but lacking the informational content of the protein?

In addition to the direct energy cost for the synthesis of a protein, there are indirect energy costs—those required for the cell to make the necessary enzymes for protein synthesis. Compare the magnitude of the indirect costs to a eukaryotic cell of the biosynthesis of linear ($\alpha 1 \rightarrow 4$) glycogen chains and the biosynthesis of polypeptides, in terms of the enzymatic machinery involved.

11. Predicting Anticodons from Codons Most amino acids have more than one codon and attach to more than one tRNA, each with a different anticodon. Write all possible anticodons for the four codons of glycine: (5′)GGU, GGC, GGA, and GGG.

(a) From your answer, which of the positions in the anticodons are primary determinants of their codon specificity in the case of glycine?

(b) Which of these anticodon-codon pairings has/have a wobbly base pair?

(c) In which of the anticodon-codon pairings do all three positions exhibit strong Watson-Crick hydrogen bonding?

12. Effect of Single-Base Changes on Amino Acid Sequence Much important confirmatory evidence on the genetic code has come from assessing changes in the amino acid sequence of mutant proteins after a single base has been changed in the gene that encodes the protein. Which of the listed amino acid replacements would be consistent with the genetic code if the replacements were caused by a single base change? Which cannot be the result of a single-base mutation? Why?

(a) Phe → Leu
(b) Lys → Ala
(c) Ala → Thr
(d) Phe → Lys
(e) Ile → Leu
(f) His → Glu
(g) Pro → Ser

13. Resistance of the Genetic Code to Mutation The RNA sequence shown represents the beginning of an open reading frame (ORF). What changes (if any) can occur at each position without generating a change in the encoded amino acid residue?

(5′)AUGAUAUUGCUAUCUUGGACU

14. Basis of the Sickle Cell Mutation Sickle cell hemoglobin has a Val residue at position 6 of the β-globin chain instead of the Glu residue found in normal hemoglobin A. Can you predict what change took place in the DNA codon for glutamate to account for replacement of the Glu residue by Val?

15. Proofreading by Aminoacyl-tRNA Synthetases The isoleucyl-tRNA synthetase has a proofreading function that ensures the fidelity of the aminoacylation reaction, but the histidyl-tRNA synthetase lacks such a proofreading function. Explain.

16. Importance of the "Second Genetic Code" Some aminoacyl-tRNA synthetases do not recognize and bind the anticodon of their cognate tRNAs but instead use other structural features of the tRNAs to impart binding specificity. The tRNAs for alanine apparently fall into this category.

(a) What features of tRNA^{Ala} does Ala-tRNA synthetase recognize?

(b) Describe the consequences of a C → G mutation in the third position of the anticodon of tRNA^{Ala}.

(c) What other kinds of mutations might have similar effects?

(d) Mutations of these types are never found in natural populations of organisms. Why? (Hint: Consider what might happen both to individual proteins and to the organism as a whole.)

17. Rate of Protein Synthesis A bacterial ribosome can synthesize about 20 peptide bonds per minute. If the average bacterial protein is approximately 260 amino acid residues long, how many proteins can the ribosomes in an *E. coli* cell synthesize in 20 minutes if all ribosomes are functioning at maximum rates?

18. The Role of Translation Factors A researcher isolates mutant variants of the bacterial translation factors IF2, EF-Tu, and EF-G. In each case, the mutation allows proper folding of the protein and the binding of GTP but does not allow GTP hydrolysis. At what stage would translation be blocked by each mutant protein?

19. Maintaining the Fidelity of Protein Synthesis The chemical mechanisms used to avoid errors in protein synthesis are different from those used during DNA replication. DNA polymerases use a $3' \rightarrow 5'$ exonuclease proofreading activity to remove mispaired nucleotides incorrectly inserted into a growing DNA strand. There is no analogous proofreading function on ribosomes, and, in fact, the identity of an amino acid attached to an incoming tRNA and added to the growing polypeptide is never checked. A proofreading step that hydrolyzed the previously formed peptide bond after insertion of an incorrect amino acid into a growing polypeptide (analogous to the proofreading step of DNA polymerases) would be impractical. Why? (Hint: Consider how the link between the growing polypeptide and the mRNA is maintained during elongation; see Figs. 27-28 and 27-29.)

20. Bacterial Protein Export Bacteria mostly use the system shown in Fig. 27-44 to export proteins out of the cell. SecB, one of the chaperone proteins found only in gram-negative bacteria, delivers a newly translated polypeptide to the SecA ATPase on the interior side of the membrane. SecA pushes the exported protein through a membrane pore formed by the SecYEG complex. The SecYEG complex is homologous to the Sec61 complex in eukaryotes. Which component of this bacterial protein export system would be the most attractive target for antibiotic development? Explain.

21. Predicting the Cellular Location of a Protein You alter the gene for a eukaryotic polypeptide 300 amino acid residues long so that a signal sequence recognized by the SRP occurs at the polypeptide's amino terminus and a nuclear localization signal (NLS) occurs internally, beginning at residue 150. Where would you likely find the protein in the cell?

22. Requirements for Protein Translocation across a Membrane The secreted bacterial protein OmpA has a precursor, ProOmpA, which has the amino-terminal signal sequence required for secretion. If you denature purified ProOmpA with 8 M urea and then remove the urea (such as by running the protein solution rapidly through a gel filtration column), the protein can translocate across isolated bacterial inner membranes in vitro. However, translocation becomes impossible if you first incubate ProOmpA for a few hours in the absence of urea. Furthermore, ProOmpA maintains its capacity for translocation for an extended period if you first incubate it in the presence of another bacterial protein called trigger factor. Describe the probable function of trigger factor.

23. Protein-Coding Capacity of a Viral DNA The 5,386 bp genome of bacteriophage ϕX174 includes genes for 10 proteins, designated A to K (omitting "I"), with sizes given in the table. How much DNA would be required to encode these 10 proteins? How can you reconcile the size of the ϕX174 genome with its protein-coding capacity?

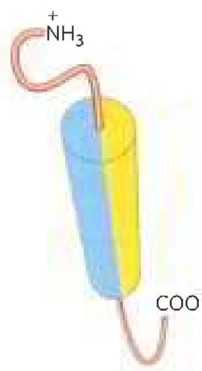
Protein	Number of amino acid residues	Protein	Number of amino acid residues
A	455	F	427
B	120	G	175
C	86	H	328
D	152	J	38
E	91	K	56

DATA ANALYSIS PROBLEM

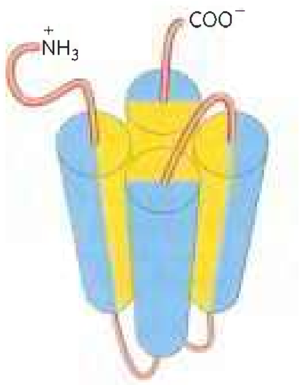
24. Designing Proteins by Using Randomly Generated Genes Studies of the amino acid sequence and corresponding three-dimensional structure of wild-type or mutant proteins have led to significant insights into the principles that govern protein folding. An important test of this understanding would be to *design* a protein based on these principles and see whether it folds as expected.

Kamtekar and colleagues (1993) used aspects of the genetic code to generate random protein sequences with defined patterns of hydrophilic and hydrophobic residues. Their clever approach combined knowledge about protein structure, amino acid properties, and the genetic code to explore the factors that influence protein structure.

The researchers set out to generate a set of proteins with the simple four-helix bundle structure shown below, with α helices (shown as cylinders) connected by segments of random coil (light red).



An amphipathic α helix



Four-helix bundle

Each α helix is amphipathic—the R groups on one side of the helix are exclusively hydrophobic (yellow), and those on the other side are exclusively hydrophilic (blue). A protein consisting of four of these helices separated by short segments of random coil would be expected to fold so that the hydrophilic sides of the helices face the solvent.

(a) What forces or interactions hold the four α helices together in this bundled structure?

Figure 4-3a shows a segment of α helix consisting of 10 amino acid residues. With the gray central rod as a divider, four of the R groups (purple spheres) extend from the left side of the helix, and six extend from the right.

(b) Number the R groups in Figure 4-3a, from top (amino terminus; 1) to bottom (carboxyl terminus; 10). Which R groups extend from the left side, and which extend from the right?

(c) Suppose you wanted to design this 10 amino acid segment to be an amphipathic helix, with the left side hydrophilic and the right side hydrophobic. Give a sequence of 10 amino acids that could potentially fold into such a structure. There are many possible correct answers.

(d) Give one possible double-stranded DNA sequence that could encode the amino acid sequence you chose for (c). (It is an internal portion of a protein, so you do not need to include start or stop codons.)

Rather than designing proteins with specific sequences, Kamtekar and colleagues designed proteins with partially random sequences, with hydrophilic and hydrophobic amino acid residues placed in a controlled pattern. They did this by taking advantage of some interesting features of the genetic code to construct a library of synthetic DNA molecules with partially random sequences arranged in a particular pattern.

To design a DNA sequence that would encode random hydrophobic amino acid sequences, the researchers began with the degenerate codon NTN, where N can be A, G, C, or T. They filled each N position by including an equimolar mixture of A, G, C, and T in the DNA synthesis reaction to generate a mixture of DNA molecules with different nucleotides at that position (see Fig. 8-32). Similarly, to encode random polar amino acid sequences, they began with the degenerate codon NAN and used an equimolar mixture of A, G, and C (but in this case, no T) to fill the N positions.

(e) Which amino acids can be encoded by the NTN triplet? Are all amino acids in this set hydrophobic? Does the set include *all* the hydrophobic amino acids?

(f) Which amino acids can be encoded by the NAN triplet? Are all of these polar? Does the set include *all* the polar amino acids?

(g) In creating the NAN codons, why was it necessary to leave T out of the reaction mixture?

Kamtekar and coworkers cloned this library of random DNA sequences into plasmids, selected 48 that produced the correct patterning of hydrophilic and hydrophobic amino acids, and expressed these in *E. coli*. The next challenge was to determine whether the proteins folded as expected. It would be very time-consuming to express each protein, crystallize it, and determine its complete three-dimensional structure. Instead, the investigators used the *E. coli* protein-processing machinery to screen out sequences that led to highly defective proteins. In this initial screening, they kept only those clones that resulted in a band of protein with the expected molecular weight on SDS polyacrylamide gel electrophoresis (see Fig. 3-18).

(h) Why would a grossly misfolded protein fail to produce a band of the expected molecular weight on electrophoresis?

Several proteins passed this initial test, and further exploration showed that they had the expected four-helix structure.

(i) Why didn't all of the random-sequence proteins that passed the initial screening test produce four-helix structures?

Chapter 28

REGULATION OF GENE EXPRESSION

28.1 The Proteins and RNAs of Gene Regulation *1055*

28.2 Regulation of Gene Expression in Bacteria *1065*

28.3 Regulation of Gene Expression in Eukaryotes *1075*

Biological information is expensive. We have discussed the extraordinary energetic cost of replication, transcription, and translation in previous chapters. The ATP requirements of converting information from a gene in a chromosome to protein imposes a need for efficiency, explaining the pervasive and often complex regulation of the expression of every gene.

Of the 4,000 or so genes in the typical bacterial genome, or the 20,000 genes in the human genome, only a fraction are expressed in a cell at any given time. Some gene products are present in very large amounts: the elongation factors required for protein synthesis, for example, are among the most abundant proteins in bacteria, and ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco) of plants and photosynthetic bacteria is one of the most abundant enzymes in the biosphere. Other gene products occur in much smaller amounts; for instance, a cell may contain only a few molecules of the enzymes that repair rare DNA lesions. Requirements for some gene products change over time. The need for enzymes in certain metabolic pathways may wax and wane as food sources change or are depleted. During development of a multicellular organism, some proteins that influence cellular differentiation are present for just a brief time in only a few cells. Specialization of cellular function can greatly affect the need for various gene products; an example is the uniquely high concentration of a single protein—hemoglobin—in erythrocytes. It is clear from these examples that the appearance of gene products must be regulated. Our exploration of the regulation of gene expression is once again guided by multiple principles:

P1 **The cellular concentration of a protein is determined by a delicate balance of at least seven processes, each having several potential points of regulation.** These processes include synthesis of the primary RNA transcript (transcription); posttranscriptional modification of mRNA; degradation of mRNA; protein synthesis (translation); posttranslational modification of proteins; protein targeting and transport; and protein degradation.

P2 **Regulation is achieved by specialized proteins and RNAs.** The proteins are usually ligand-binding proteins with no other function. They bind to specific sequences in DNA or RNA. They respond to molecular signals that can be any kind of biological molecule. The RNAs either interact with other RNAs or serve as protein cofactors.

P3 **Regulated gene expression may bring about increases or decreases in the amount of a gene product.** Gene products that increase in concentration under particular molecular circumstances are referred to as **inducible**; the process of increasing their expression is **induction**. Conversely, gene products that decrease in concentration in response to a molecular signal are referred to as **repressible**, and the process is called **repression**.

P4 **The default transcriptional state of a gene, on or off, is dictated in part by the size and complexity of the genome.** In bacteria, where genomes are relatively small and DNA is readily accessible, the default state of genes is generally "on." Transcription of each gene or gene cluster is usually limited by a specific protein repressor. In eukaryotes, where genomes are larger and genes are encapsulated in chromatin, the default state of most genes is "off." Gene transcription requires chromatin modification followed by the action of transcription activators.

P5 **Regulation is expensive.** For many genes, especially in eukaryotes, the regulatory processes can require a considerable investment of chemical energy. That expenditure is nevertheless small when compared to the cost of RNA and protein synthesis when the gene is expressed.

P1 The steps required to generate and then remove an active protein or RNA, all of which may be regulated, are summarized in **Figure 28-1**. We have examined several of the relevant regulatory mechanisms in previous chapters. Posttranscriptional modification of mRNA, by processes such as alternative splicing patterns (see Fig. 26-20) or RNA editing (see Figs 27-10 and 27-12), can affect which proteins are produced from an mRNA transcript and in what amounts. A variety of nucleotide sequences in an mRNA can affect the rate of its degradation (p. 986). Many factors affect the rate at which an mRNA is translated into a protein, as well as the posttranslational modification, targeting, and eventual degradation of that protein (Chapter 27).

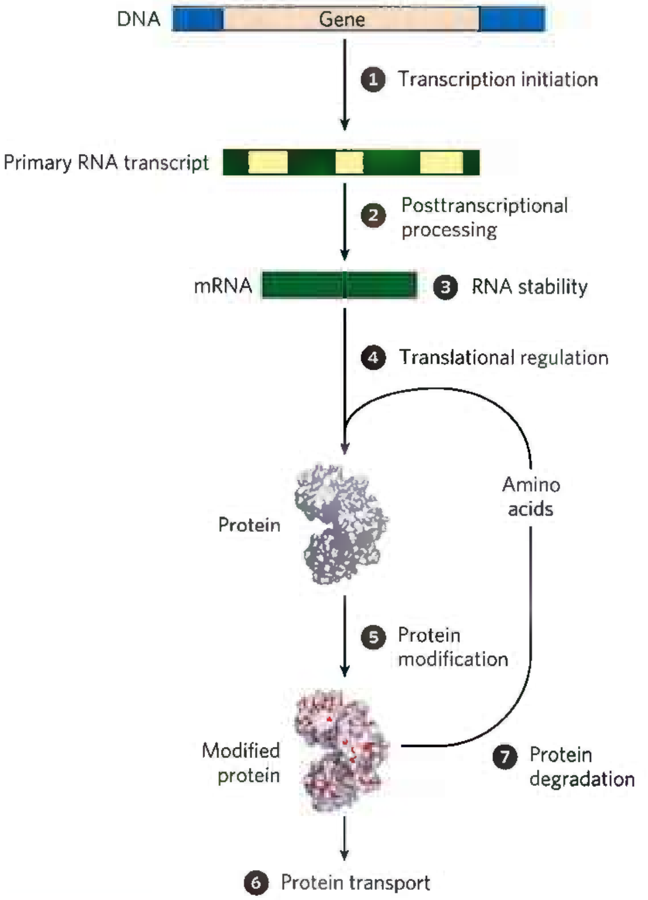

FIGURE 28-1 Seven processes that affect the steady-state concentration of a protein. Each process has several potential points of regulation.

Of the regulatory processes illustrated in Figure 28-1, those operating at the level of transcription initiation are particularly well-documented. These processes are a major focus of this chapter, although we also consider other mechanisms. As noted in earlier chapters, the complexity of an organism is not reflected in the number of its protein-coding genes. Instead, as complexity increases from bacteria to mammals, mechanisms of gene regulation become more elaborate, and posttranscriptional and translational regulation play greater roles.

Control of transcription initiation permits the synchronized regulation of multiple genes encoding products with interdependent activities. For example, when their DNA is heavily damaged, bacterial cells require a coordinated increase in the levels of the many DNA repair enzymes. And perhaps the most sophisticated form of coordination occurs in the complex regulatory circuits that guide the development of multicellular eukaryotes, which can include many types of regulatory mechanisms.

We begin by examining the interactions between proteins and DNA that are the key to transcriptional regulation. We next discuss the specific proteins that influence the expression of specific genes, first in bacterial and then in eukaryotic cells. Information about posttranscriptional and translational controls is included in the discussion, where relevant, to provide a more complete overview of the rich complexity of cellular regulation.

28.1 The Proteins and RNAs of Gene Regulation

Transcription is mediated and regulated by protein-DNA interactions, especially those involving the protein components of RNA polymerase (Chapter 26). We first consider how the activity of RNA polymerase is regulated. Next, we proceed to a general description of the proteins participating in this regulation. We then examine the molecular basis for the recognition of specific DNA sequences by DNA-binding proteins. Regulatory RNAs are encountered most often in the regulation of mRNA translation in eukaryotes, but also play a role in the life of some bacterial mRNAs. We consider them briefly in this section, and in more detail in Section 28.3.

RNA Polymerase Binds to DNA at Promoters

RNA polymerases bind to DNA and initiate transcription at promoters (see Fig. 26-5), sites generally found near points at which RNA synthesis begins on the DNA template. The regulation of transcription initiation often entails changes in how RNA polymerase interacts with a promoter.

The nucleotide sequences of promoters vary considerably, affecting the binding affinity of RNA polymerases

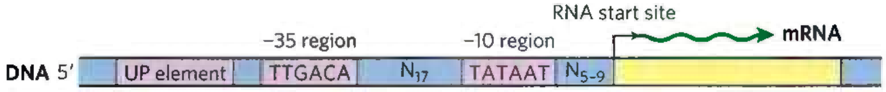

FIGURE 28-2 Consensus sequence for many *E. coli* promoters. Most base substitutions in the −10 and −35 regions have a negative effect on promoter function. Some promoters also include the UP (upstream promoter) element.

and thus the frequency of transcription initiation. Some *Escherichia coli* genes are transcribed once per second, others less than once per cell generation. Much of this variation is due to differences in promoter sequence. In the absence of regulatory proteins, differences in promoter sequence may affect the frequency of transcription initiation by a factor of 1,000 or more. Most *E. coli* promoters have a sequence close to a consensus (**Fig. 28-2**). Mutations that result in a shift away from the consensus sequence usually decrease the function of bacterial promoters; conversely, mutations toward consensus usually enhance promoter function.

KEY CONVENTION By convention, DNA sequences are shown as they exist in the nontemplate strand, with the 5′ terminus on the left. Nucleotides are numbered from the transcription start site, with positive numbers to the right (in the direction of transcription) and negative numbers to the left. N indicates any nucleotide. ■

Genes for products that are required at all times, such as those for the enzymes of central metabolic pathways, are expressed continuously, with little variation in virtually every cell of a species or organism. Such genes are often referred to as **housekeeping genes**. Expression of a gene at approximately constant levels is called **constitutive gene expression**. Although housekeeping genes are expressed constitutively, the cellular concentrations of the proteins they encode vary widely. For these genes, the RNA polymerase–promoter interaction strongly influences the rate of transcription initiation. Differences in promoter sequence may be the only level of regulation for a housekeeping gene, allowing the cell to synthesize the appropriate level of each housekeeping gene product.

The basal rate of transcription initiation at the promoters of nonhousekeeping genes is also determined by the promoter sequence, but expression of these genes is further modulated by regulatory proteins. Many of these proteins work by enhancing or interfering with the interaction between RNA polymerase and the promoter.

The sequences of eukaryotic promoters are much more variable than their bacterial counterparts. The three eukaryotic RNA polymerases usually require an array of general transcription factors in order to bind to a promoter, and these can heavily influence basal transcription rates. Yet, as with bacterial gene expression, the basal level of transcription is determined in part by the effect of promoter sequences on the function of RNA polymerase and its associated transcription factors.

Transcription Initiation Is Regulated by Proteins and RNAs

P2 At least three types of regulatory proteins regulate transcription initiation by RNA polymerase: **specificity factors** alter the specificity of RNA polymerase for a given promoter or set of promoters, **repressors** impede access of RNA polymerase to the promoter, and **activators** enhance the RNA polymerase–promoter interaction.

As our understanding of the roles of protein regulators slowly matures, many new roles for gene regulation by **noncoding RNAs (ncRNAs)** are also beginning to emerge. Among these are the **long noncoding RNAs (lncRNAs)**, generally defined as noncoding RNAs more than 200 nucleotides long that lack an open reading frame (ORF) that encodes a protein—thus distinguishing them from the small, functional ncRNAs (miRNA, snoRNA, snRNA, etc.) described in Chapter 26. The lncRNAs are found in all types of organisms, with tens of thousands expressed in mammalian cells. Known functions of lncRNAs include regulation of nucleosome positioning and chromatin structure, control of DNA methylation and posttranscriptional histone modifications, transcriptional gene silencing, multiple roles in transcriptional activation and repression, and much more.

We introduced bacterial specificity factors in Chapter 26, although we did not refer to these proteins by that name. The σ subunit of the *E. coli* RNA polymerase holoenzyme is a specificity factor that mediates promoter recognition and binding. Most *E. coli* promoters are recognized by a single σ subunit (M_r 70,000), σ^{70} (see Fig. 26-5). Under some conditions, some of the σ^{70} subunits are replaced by one of six other specificity factors. One notable case arises when bacteria are subjected to heat stress, leading to the replacement of σ^{70} by σ^{32} (M_r 32,000). When bound to σ^{32}, RNA polymerase is directed to a specialized set of promoters with a different consensus sequence (**Fig. 28-3**). These promoters control the

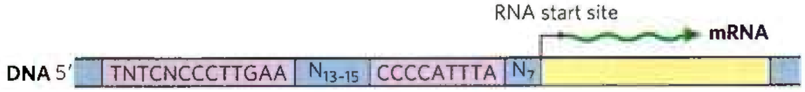

FIGURE 28-3 Consensus sequence for promoters that regulate expression of the *E. coli* heat shock genes. This system responds to temperature increases as well as some other environmental stresses, resulting in the induction of a set of proteins. Binding of RNA polymerase to heat shock promoters is mediated by a specialized σ subunit of the polymerase, σ^{32}, which replaces σ^{70} in the RNA polymerase initiation complex.

expression of a set of genes that encode proteins, including some protein chaperones (p. 132), that are part of a stress-induced system called the heat shock response. Thus, through changes in the binding affinity of the polymerase that direct the enzyme to different promoters, a set of genes involved in related processes is coordinately regulated. In eukaryotic cells, some of the general transcription factors, in particular the TATA-binding protein (TBP; see Fig. 26-9), may be considered specificity factors.

Repressors bind to specific sites on the DNA. In bacterial cells, such binding sites, called **operators**, are generally near a promoter. RNA polymerase binding, or its movement along the DNA after binding, is blocked when the repressor is present. **P3** Regulation by means of a repressor protein that blocks transcription is referred to as **negative regulation**. Repressor binding to DNA is regulated by a molecular signal, or **effector**, usually a small molecule or a protein that binds to the repressor and causes a conformational change. The interaction between repressor and signal molecule either increases or decreases transcription. In some cases, the conformational change results in dissociation of a DNA-bound repressor from the operator (**Fig. 28-4a**). Transcription initiation can then proceed unhindered. In other cases, interaction between an inactive repressor and the signal molecule causes the repressor to bind to the operator (Fig. 28-4b). **P4** In eukaryotic cells, gene regulation by a repressor is less common. Where it does occur (more often in lower eukaryotes such as yeast), the binding site for a repressor may be some distance from the promoter. Binding of these repressors to their binding sites has the same effect as in bacterial cells: inhibiting the assembly or activity of a transcription complex at the promoter.

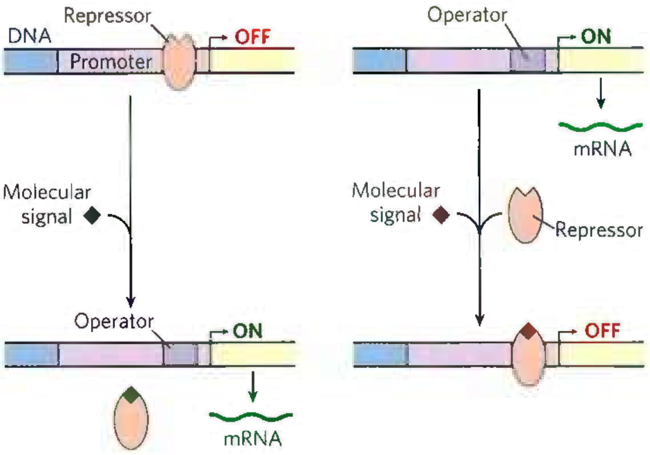
P3 Activators provide a molecular counterpoint to repressors; they bind to DNA and *enhance* the activity of RNA polymerase at a promoter; this is **positive regulation**. In bacteria, activator-binding sites are often adjacent to promoters that are bound weakly or not at all by RNA polymerase alone, such that little transcription occurs in the absence of the activator. Some activators are usually bound to DNA, enhancing transcription until dissociation of the activator is triggered by the binding of a signal molecule (Fig. 28-4c). In other cases the activator binds to DNA only after interaction with a signal molecule (Fig. 28-4d). Signal molecules can therefore increase or decrease transcription, depending on how they affect the activator.

P4 Positive regulation by activators is particularly common in eukaryotes. Many eukaryotic activators bind to DNA sites, called enhancers, that are distant from the promoter, affecting the rate of transcription at a promoter that may be located thousands of base pairs away.

The distance between a promoter and the binding site of an activator or repressor is bridged by looping out of the DNA between the two sites (**Fig. 28-5**). The looping is facilitated in some cases by proteins called **architectural regulators** that bind to intervening sites. Interaction between activators and the RNA polymerase at the promoter is often mediated by intermediary proteins called coactivators. In some instances, protein repressors may take the place of coactivators, binding to the activators and preventing the activating interaction.

(a) Negative regulation
Molecular signal causes dissociation of repressor from DNA, inducing transcription.

(b) Negative regulation
Molecular signal causes binding of repressor to DNA, inhibiting transcription.



(c) Positive regulation
Molecular signal causes dissociation of activator from DNA, inhibiting transcription.

(d) Positive regulation
Molecular signal causes binding of activator to DNA, inducing transcription.

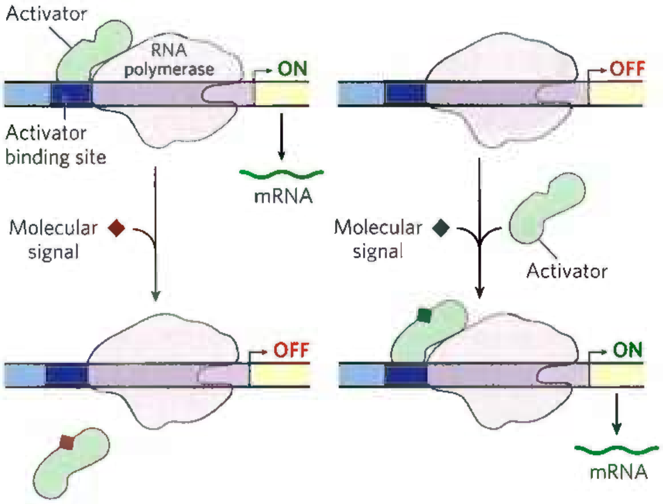


FIGURE 28-4 Common patterns of regulation of transcription initiation. Two types of negative regulation are illustrated. (a) Repressor binds to the operator in the absence of the molecular signal; the external signal causes dissociation of the repressor to permit transcription. (b) Repressor binds in the presence of the signal; the repressor dissociates, and transcription ensues when the signal is removed. Positive regulation is mediated by gene activators. Again, two types are shown. (c) Activator binds in the absence of the molecular signal and transcription proceeds; when the signal is added, the activator dissociates and transcription is inhibited. (d) Activator binds in the presence of the signal; it dissociates only when the signal is removed. Note that "positive" regulation and "negative" regulation refer to the type of regulatory protein involved: the bound protein either facilitates or inhibits transcription. In either case, addition of the molecular signal may increase or decrease transcription, depending on its effect on the regulatory protein.

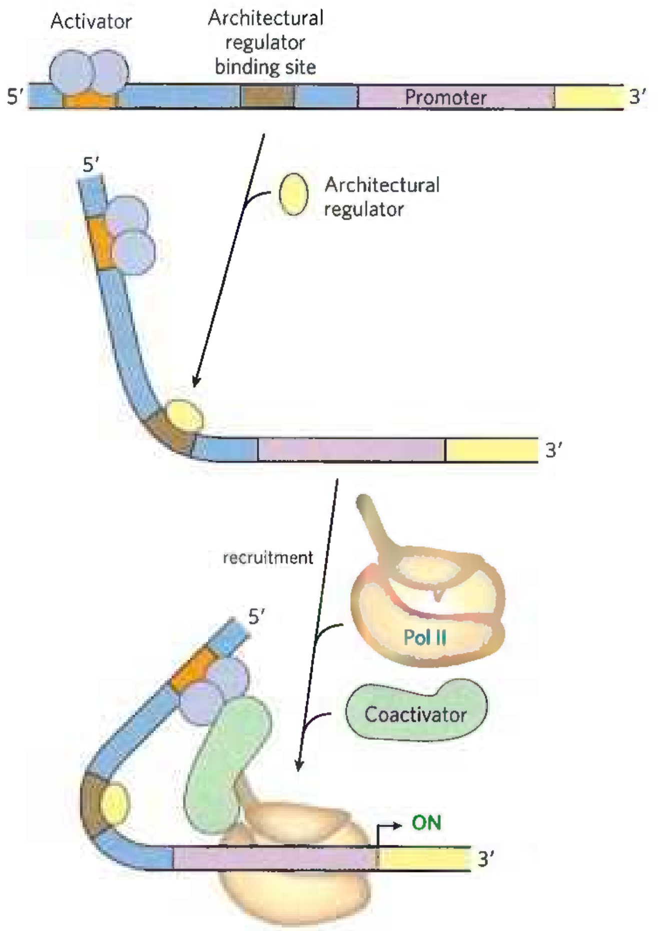

FIGURE 28-5 Interaction between activators/repressors and RNA polymerase in eukaryotes. Eukaryotic activators and repressors frequently bind sites thousands of base pairs distant from the promoters they regulate. DNA looping, often facilitated by architectural regulators, brings the sites together. The interaction between activators and RNA polymerase may be mediated by coactivators, as shown. Repression is sometimes mediated by repressors (described later) that bind to activators, thereby preventing the activating interaction with RNA polymerase.

Many Bacterial Genes Are Clustered and Regulated in Operons

Bacteria have a simple general mechanism for coordinating the regulation of multiple genes: these genes are clustered on the chromosome and are transcribed together. Many bacterial mRNAs are polycistronic—multiple genes on a single transcript—and the single promoter that initiates transcription of the cluster is the site of regulation for expression of all the genes in the cluster. The gene cluster and promoter, plus additional sequences that function together in regulation, are called an **operon** (**Fig. 28-6**). Operons that include two to six genes transcribed as a unit are common; some operons contain 20 or more genes. The identity and order of the genes in an operon are not random. In many cases, genes in the same operon encode subunits of a larger protein complex, and cotranslation directly enables assembly of the complex. Some operons organize genes involved in related processes that require coordinated regulation. In other cases, the genes may seem to be unrelated, but they encode products required by the cell under similar conditions.

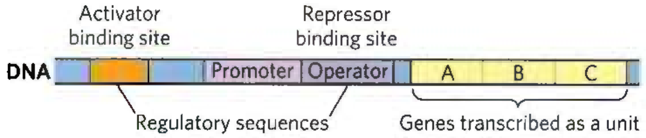

FIGURE 28-6 Representative bacterial operon. Genes A, B, and C are transcribed on one polycistronic mRNA. Typical regulatory sequences include binding sites for proteins that either activate or repress transcription from the promoter.

Many of the principles of bacterial gene expression were first defined by studies of lactose metabolism in *E. coli*, which can use lactose as its sole carbon source. In 1960, François Jacob and Jacques Monod published a short paper in the *Proceedings of the French Academy of Sciences* that described how two adjacent genes involved in lactose metabolism were coordinately regulated by a genetic element located at one end of the gene cluster. The genes were those for β-galactosidase, which cleaves lactose to galactose and glucose, and for galactoside permease, which transports lactose into the cell (**Fig. 28-7**). The terms "operon" and "operator" were first introduced in this paper. With the operon model, gene regulation could, for the first time, be considered in molecular terms.

The *lac* Operon Is Subject to Negative Regulation

The lactose (*lac*) operon (**Fig. 28-8a**) includes the genes for β-galactosidase (Z), galactoside permease (Y), and thiogalactoside transacetylase (A). The last of these enzymes seems to modify toxic galactosides to facilitate their removal from the cell. Each of the three genes is preceded by a ribosome-binding site (not shown in Fig. 28-8) that independently directs the translation of that gene (Chapter 27). Regulation of the *lac* operon by the *lac* repressor protein (Lac) follows the pattern outlined in Figure 28-4a.

The study of *lac* operon mutants has revealed some details of the workings of the operon's regulatory system. In the absence of lactose, the *lac* operon genes are repressed. Mutations in the operator or in another gene, the *I* gene, result in constitutive synthesis of the gene products. When the *I* gene is defective, repression can be restored by introducing a functional *I* gene into the cell on another DNA molecule, demonstrating that the *I* gene encodes a diffusible molecule that causes gene repression. This molecule proved to be a protein, now called the Lac repressor, a tetramer of identical monomers. The operator to which it binds most tightly (O_1) abuts the transcription start site (Fig. 28-8a). The *I* gene is transcribed from its own promoter (P_I) independent of the *lac* operon genes. The *lac* operon has two secondary

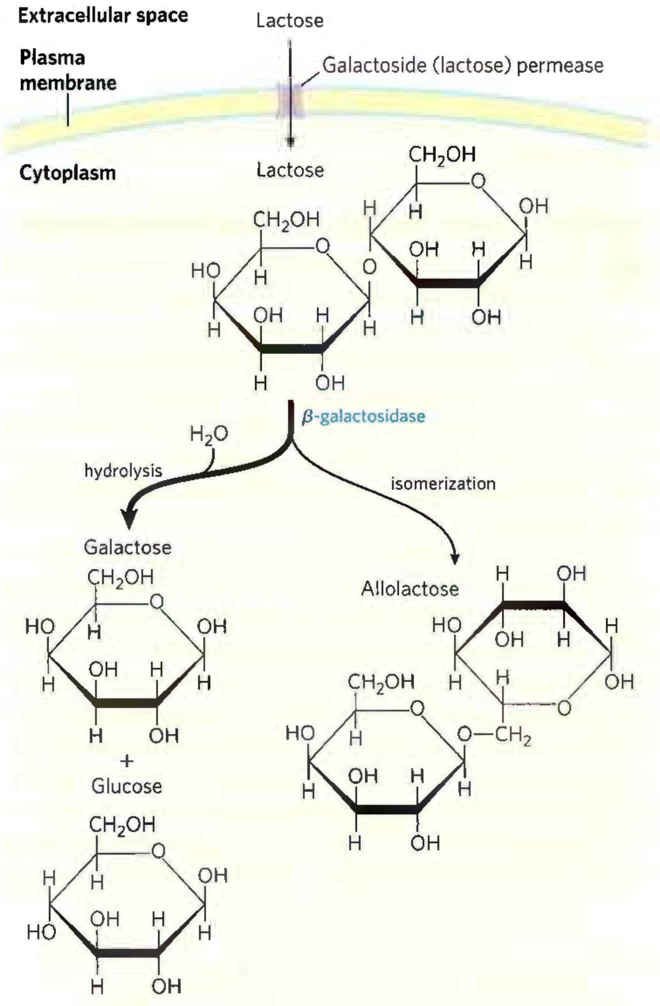

FIGURE 28-7 Lactose metabolism in *E. coli*. Uptake and metabolism of lactose require the activities of galactoside (lactose) permease and β-galactosidase. Conversion of lactose to allolactose by transglycosylation is a minor reaction also catalyzed by β-galactosidase.

binding sites for the Lac repressor: O_2 and O_3. O_2 is centered near position +410, within the gene encoding β-galactosidase (*Z*); O_3 is near position –90, within the *I* gene. To repress the operon, the Lac repressor seems to bind to both the main operator and one of the two secondary sites, with the intervening DNA looped out (Fig. 28-8b, c). Either binding arrangement blocks transcription initiation.

Despite this elaborate binding complex, repression is not absolute. Binding of the Lac repressor reduces the rate of transcription initiation by a factor of 10^3. If the O_2 and O_3 sites are eliminated by deletion or mutation, the binding of repressor to O_1 alone reduces transcription by a factor of about 10^2. Even in the repressed state, each cell has a few molecules of β-galactosidase and galactoside permease, presumably synthesized on the rare occasions when the repressor transiently dissociates from the operators. This basal level of transcription is essential to operon regulation.

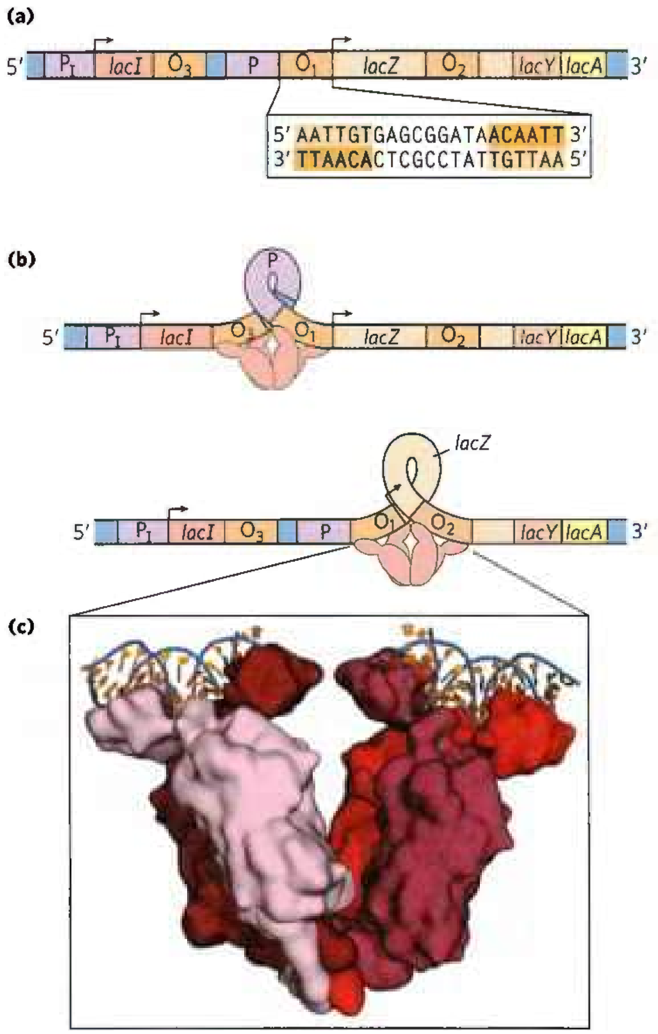

FIGURE 28-8 The *lac* operon. (a) In the *lac* operon, the *lacI* gene encodes the Lac repressor. The *lac Z*, *Y*, and *A* genes encode β-galactosidase, galactoside permease, and thiogalactoside transacetylase, respectively. P is the promoter for the *lac* genes, and P_I is the promoter for the *I* gene. O_1 is the main operator for the *lac* operon; O_2 and O_3 are secondary operator sites of lesser affinity for the Lac repressor. The inverted repeat to which the Lac repressor binds in O_1 is shown. (b) The Lac repressor binds to the main operator and O_2 or O_3, and it seems to form a loop in the DNA. (c) Lac repressor (shades of red) is shown bound to short, discontinuous segments of DNA (blue and orange). [(c) Data from PDB ID 2PE5, R. Daber et al., *J. Mol. Biol.* 370:609, 2007.]

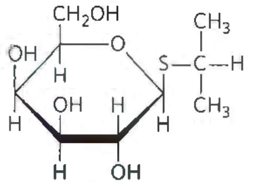
When cells are provided with lactose, the *lac* operon is induced. An inducer (signal) molecule binds to a specific site on the Lac repressor, causing a conformational change that results in dissociation of the repressor from the operator. The inducer in the *lac* operon system is not lactose itself but allolactose, an isomer of lactose (Fig. 28-7). After entry into the *E. coli* cell (via the few preexisting molecules of lactose permease), lactose is converted to allolactose by one of the few preexisting β-galactosidase molecules. Release of the operator by Lac repressor, triggered as the repressor binds to allolactose, allows expression of the *lac* operon genes and leads to a 10^3-fold increase in the concentration of β-galactosidase.

Several β-galactosides structurally related to allolactose are inducers of the *lac* operon but are not substrates for β-galactosidase; others are substrates but not inducers. One particularly effective and nonmetabolizable inducer of the *lac* operon that is often used experimentally is isopropylthiogalactoside (IPTG).



Isopropyl-β-D-thiogalactoside (IPTG)

An inducer that cannot be metabolized allows researchers to explore the physiological function of lactose as a carbon source for growth, separate from its function in the regulation of gene expression.

In addition to the multitude of operons now known in bacteria, a few polycistronic operons have been found in the cells of lower eukaryotes. In the cells of higher eukaryotes, however, almost all protein-coding genes are transcribed separately.

The mechanisms by which operons are regulated can vary significantly from the simple model presented in Figure 28-8. Even the *lac* operon is more complex than indicated here, with an activator also contributing to the overall scheme, as we shall see in Section 28.2. Before any further discussion of the layers of regulation of gene expression, however, we examine the critical molecular interactions between DNA-binding proteins (such as repressors and activators) and the DNA sequences to which they bind.

Regulatory Proteins Have Discrete DNA-Binding Domains

P2 Regulatory proteins generally bind to specific DNA sequences. Their affinity for these target sequences is roughly 10^4 to 10^6 times higher than their affinity for any other DNA sequence. Most regulatory proteins have discrete DNA-binding domains containing substructures that interact closely and specifically with the DNA. These binding domains usually include one or more of a relatively small group of recognizable and characteristic structural motifs.

To bind specifically to DNA sequences, regulatory proteins must recognize surface features on the DNA (see Fig. 8-13). Most of the chemical groups that differ among the four bases and thus permit discrimination between base pairs are hydrogen-bond donor and acceptor groups exposed in the major groove of DNA (**Fig. 28-9**), and most of the protein-DNA contacts that impart specificity are hydrogen bonds. A notable exception is the nonpolar surface near C-5 of pyrimidines, where thymine is readily distinguished from cytosine by its protruding methyl group. Protein-DNA contacts are also possible in the

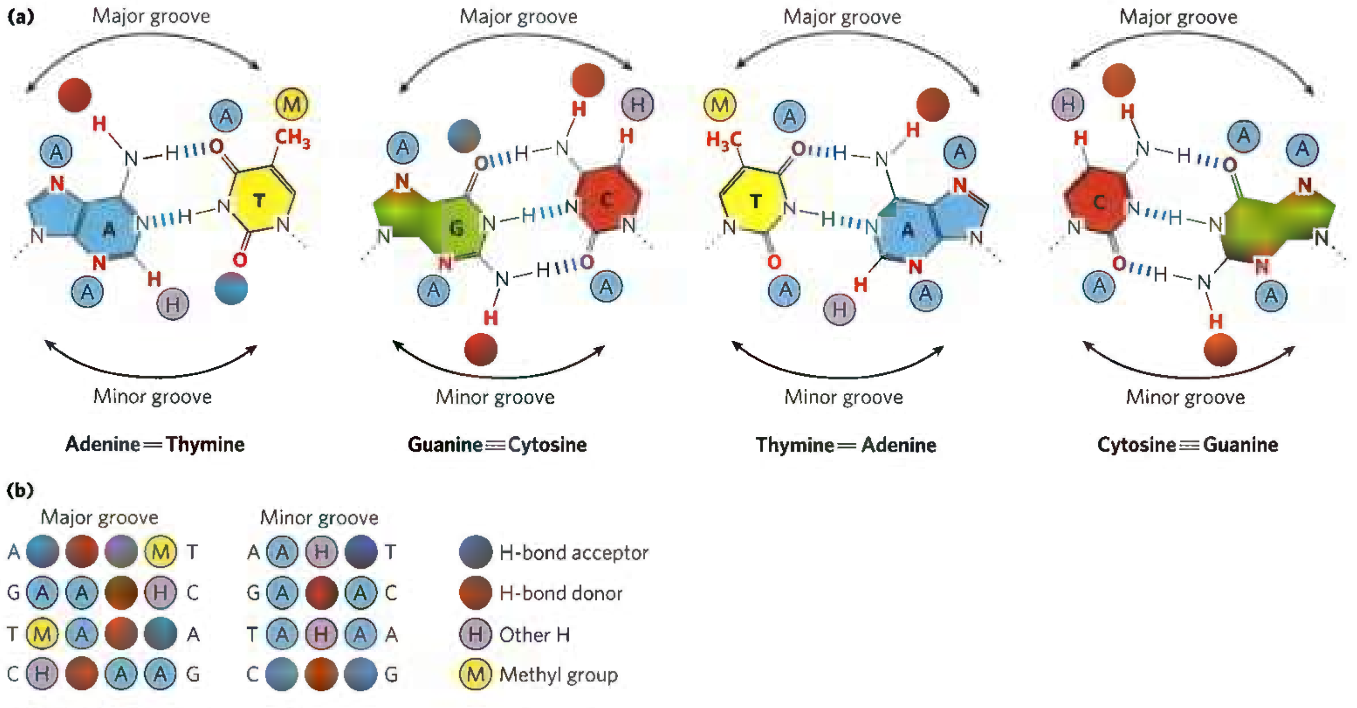


FIGURE 28-9 Groups in DNA available for protein binding. (a) Shown here are functional groups on all four base pairs that are displayed in the major and minor grooves of DNA. Hydrogen-bond acceptor (A) and donor (D) atoms are marked by blue and red disks, respectively. Other hydrogen atoms (H) are marked with purple disks, and methyl groups (M) with yellow disks. (b) Recognition patterns for each base pair (from left to right). The much greater variation in the patterns for the major groove gives rise to a much greater discriminatory power in the major groove relative to the minor groove. [Information from J. L. Huret, *Atlas Genet. Cytogenet. Oncol. Haematol.* 2006, http://atlasgeneticsoncology.org/Educ/DNAEngID30001ES.html.]

minor groove of the DNA, but the hydrogen-bonding patterns there generally do not allow ready discrimination between base pairs.

Within regulatory proteins, the amino acid side chains most often hydrogen-bonding to bases in the DNA are those of Asn, Gln, Glu, Lys, and Arg residues. Is there a simple recognition code in which a particular amino acid always pairs with a particular base? The two hydrogen bonds that can form between Gln or Asn and the N^6 and N-7 positions of adenine cannot form with any other base. And an Arg residue can form two hydrogen bonds with N-7 and O^6 of guanine (**Fig. 28-10**). Examination of the structure of many DNA-binding proteins, however, has shown that a protein can recognize each base pair in more than one way, leading to the conclusion that there is no simple amino acid–base code. For some proteins, the Gln-adenine interaction can specify A═T base pairs, but in others a van der Waals pocket for the methyl group of thymine can recognize A═T base pairs. Researchers cannot yet examine the structure of a DNA-binding protein and infer the DNA sequence to which it binds.

To interact with bases in the major groove of DNA, a protein requires a relatively small substructure that can stably protrude from the protein surface. The DNA-binding domains of regulatory proteins tend to be small (60 to 90 amino acid residues), and the structural motifs within these domains that are actually in contact with the DNA are smaller still. Many small proteins are unstable because of their limited capacity to form layers of structure to bury hydrophobic groups. The DNA-binding motifs provide either a very compact stable structure or a way of allowing a segment of protein to protrude from the protein surface.

P2 The DNA-binding sites for regulatory proteins are often inverted repeats of a short DNA sequence (a palindrome) at which multiple (usually two) subunits of a regulatory protein bind cooperatively. The Lac repressor is unusual in that it functions as a tetramer, with two dimers tethered together at the end distant from the DNA-binding sites (Fig. 28-8b). An *E. coli* cell usually contains about 20 tetramers of the Lac repressor. Each of the tethered dimers separately binds to a palindromic operator sequence, in contact with 17 bp of a 22 bp region in the *lac* operon. And each of the tethered dimers can independently bind to an operator sequence, with one generally binding to O_1 and the other to O_2 or O_3 (as in Fig. 28-8b). The symmetry of the O_1 operator sequence corresponds to the twofold axis of symmetry of two paired Lac repressor subunits. The tetrameric Lac repressor binds to its operator sequences in vivo with an estimated dissociation constant of 10^{-10} M. The repressor discriminates between the operators and other sequences by a factor of about 10^6, so binding to these few base pairs among the 4.6 million or so of the *E. coli* chromosome is highly specific.

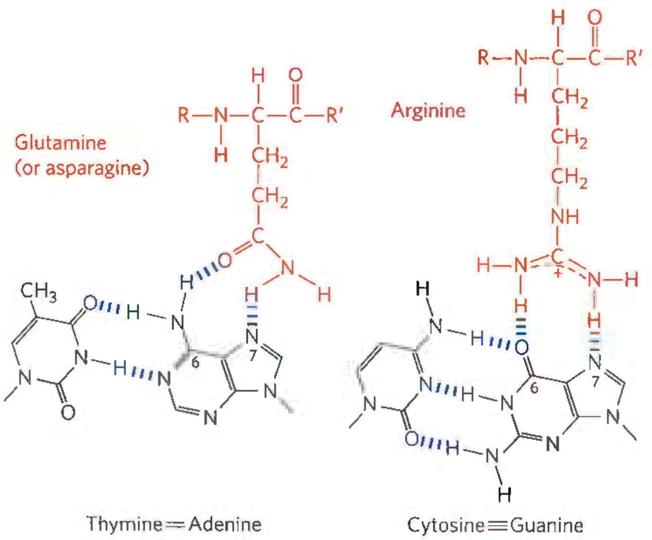

FIGURE 28-10 Specific amino acid residue–base pair interactions. The two examples shown have been observed in DNA-protein binding.

Several DNA-binding motifs have been described, but here we focus on two that play prominent roles in the binding of DNA by regulatory proteins from all domains of life: the helix-turn-helix and the zinc finger. We also consider two other types of such motifs: the homeodomain and the RNA recognition motif, which, as its name implies, also binds RNA; both motifs play prominent roles in some eukaryotic regulatory proteins.

Helix-Turn-Helix The **helix-turn-helix** motif is crucial to the interaction of many regulatory proteins with DNA in bacteria, and similar motifs occur in some eukaryotic regulatory proteins. The helix-turn-helix comprises about 20 amino acid residues in two short α-helical segments, each 7 to 9 residues long, separated by a β turn (**Fig. 28-11**). This structure generally is not stable by itself; it is simply the interactive portion of a somewhat larger DNA-binding domain. One of the two α-helical segments is called the recognition helix, because it usually contains many of the amino acids that interact with DNA in a sequence-specific way. This α helix is stacked on other segments of the protein structure so that it protrudes from the protein surface. When bound to DNA, the recognition helix is positioned in or nearly in the major groove. The Lac repressor has this DNA-binding motif.

Zinc Finger In a **zinc finger**, about 30 amino acid residues form an elongated loop held together at the base by a single Zn^{2+} ion, which is coordinated to 4 of the residues (4 Cys, or 2 Cys and 2 His). The zinc does not itself interact with DNA; rather, the coordination of zinc with the amino acid residues stabilizes this small structural motif. Several hydrophobic side chains in the core of the structure also lend stability. **Figure 28-12** shows the interaction between DNA and three zinc fingers of a single polypeptide from the mouse regulatory protein Zif268.

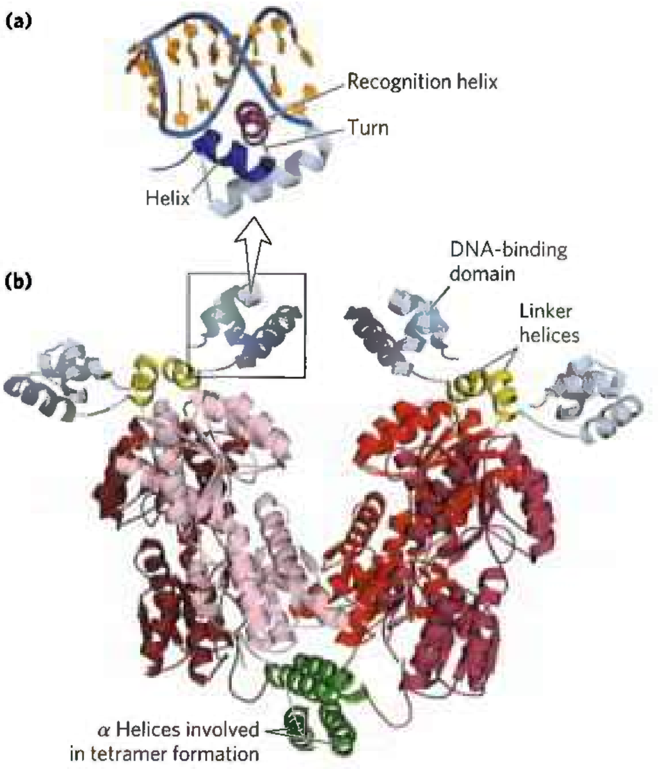

FIGURE 28-11 Helix-turn-helix. (a) DNA-binding domain of the Lac repressor bound to DNA. (b) The entire Lac repressor. The DNA-binding domains and the α helices involved in tetramer formation are labeled. The remainder of the protein has the binding sites for allolactose. The allolactose-binding domains are linked to the DNA-binding domains through linker helices. [Data from PDB ID 2PE5, R. Daber et al., *J. Mol. Biol.* 370:609, 2007.]

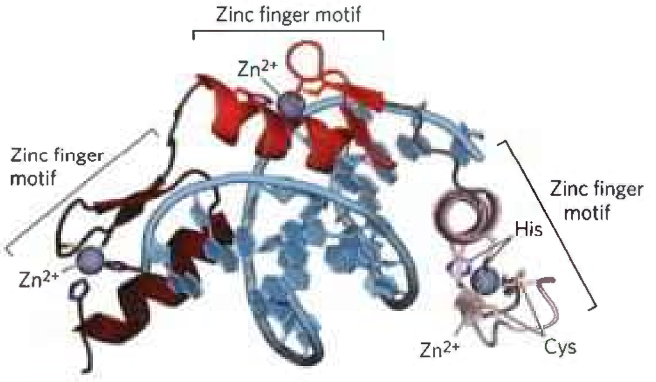

FIGURE 28-12 Zinc fingers. Three zinc fingers of the regulatory protein Zif268, complexed with DNA. Each Zn^{2+} coordinates with two His and two Cys residues. [Data from PDB ID 1ZAA, N. P. Pavletich and C. O. Pabo, *Science* 252:809, 1991.]

Many eukaryotic DNA-binding proteins contain zinc fingers. The interaction of a single zinc finger with DNA is typically weak, and many DNA-binding proteins, like Zif268, have multiple zinc fingers that substantially enhance binding by interacting simultaneously with the DNA. One DNA-binding protein of the frog *Xenopus* has 37 zinc fingers. There are few known examples of the zinc finger motif in bacterial proteins.

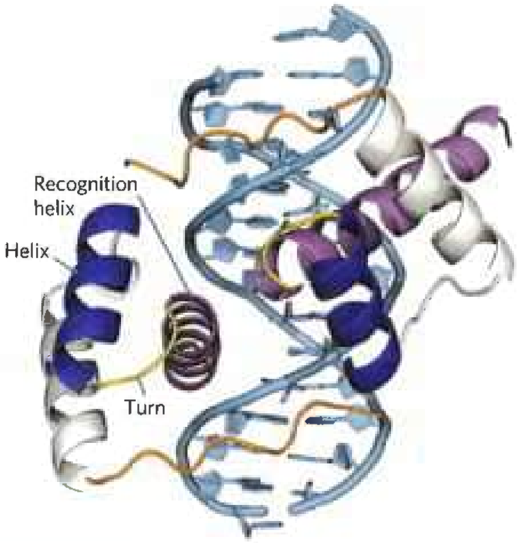

FIGURE 28-13 Homeodomains. Shown here are two homeodomains bound to DNA. In each homeodomain, the recognition helix, layered on two others, can be seen protruding into the major groove. This is only a small part of a larger regulatory protein from a class called Pax, active in the regulation of development in fruit flies (see Section 28.3). [Data from PDB ID 1FJL, D. S. Wilson et al., *Cell* 82:709, 1995.]

The precise manner in which proteins with zinc fingers bind to DNA differs from one protein to the next. Some zinc fingers contain the amino acid residues that are important in sequence discrimination, whereas others seem to bind DNA nonspecifically (the amino acids required for specificity are located elsewhere in the protein). Zinc fingers can also function as RNA-binding motifs, such as in certain proteins that bind eukaryotic mRNAs and act as translational repressors. We discuss this role later (Section 28.3).

Homeodomain Another type of DNA-binding domain has been identified in some proteins that function as transcriptional regulators, especially during eukaryotic development. This domain of 60 amino acid residues—called the **homeodomain**, because it was discovered in homeotic genes (genes that regulate the development of body patterns)—is highly conserved and has now been identified in proteins from a wide variety of organisms, including humans (Fig. 28-13). The DNA-binding segment of the domain is related to the helix-turn-helix motif. The DNA sequence that encodes this domain is known as the **homeobox**.

RNA Recognition Motif New classes of proteins with RNA-binding domains continue to be identified. **RNA recognition motifs (RRMs)** are found in some eukaryotic gene activators, where they may do double duty in binding DNA and RNA. When bound to specific binding sites in DNA, these activators induce transcription. The same activators are sometimes regulated in part by specific lncRNAs that compete with DNA binding and decrease gene transcription. Other proteins with RRM motifs bind to mRNA, rRNA, or any of a range of other smaller, noncoding RNAs. The RRM consists of 90 to 100 amino acid residues, arranged in a four-strand antiparallel β sheet sandwiched against two α helices, with a β_1-α_1-β_2-β_3-α_2-β_4 topology (**Fig. 28-14a**). This motif may be present as part of DNA-binding regulatory proteins that also have other DNA-binding motifs or may occur in proteins that bind uniquely to RNA. The RRM is just one of many diverse protein motifs known to interact with RNA (Fig. 28-14b).

Regulatory Proteins Also Have Protein-Protein Interaction Domains

Regulatory proteins contain domains not only for DNA binding but also for protein-protein interactions—with RNA polymerase, other regulatory proteins, or other subunits of the same regulatory protein. Examples include many eukaryotic transcription factors that function as gene activators, which often bind as dimers to the DNA through DNA-binding domains that contain zinc fingers. Some structural domains are devoted to the interactions required for dimer formation, which is generally a prerequisite for DNA binding. Like DNA-binding motifs, the structural motifs that mediate protein-protein interactions tend to fall within one of a few common categories. Two important examples are the leucine zipper and the basic helix-loop-helix. Structural motifs such as these are the basis for classifying some regulatory proteins into structural families.

Leucine Zipper The **leucine zipper** is an amphipathic α helix with a series of hydrophobic amino acid residues concentrated on one side (**Fig. 28-15**), with the hydrophobic surface forming the area of contact between the two polypeptides of a dimer. A striking

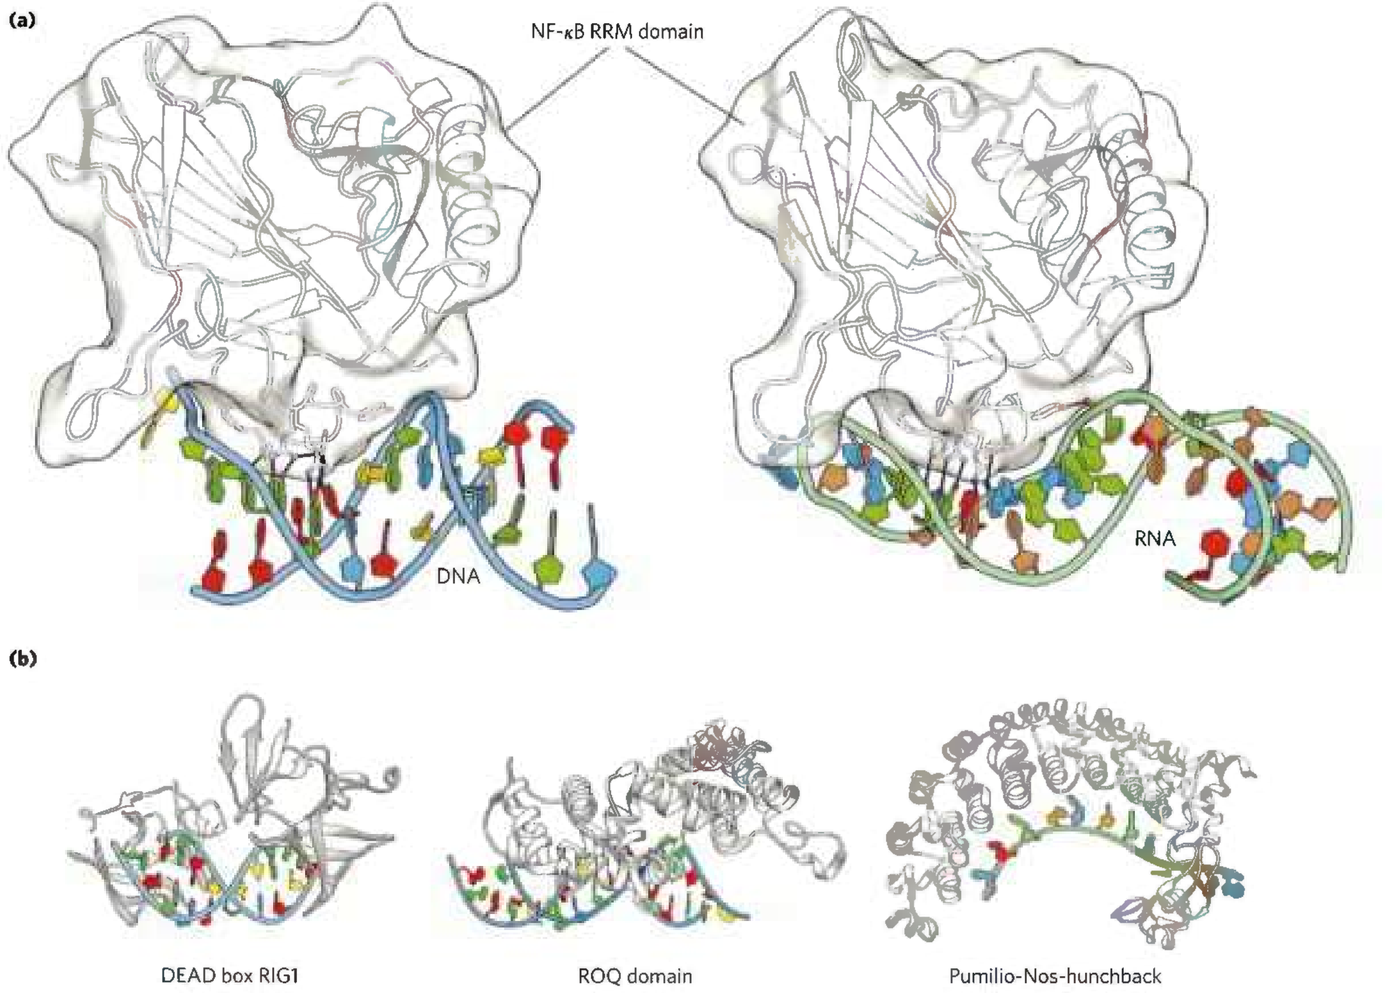

FIGURE 28-14 **RNA recognition motifs (RRMs).** (a) An RRM from the p50 subunit of regulatory protein NF-κB is shown, bound to (left) DNA and (right) RNA. Black lines indicate hydrogen-bonding interactions between particular amino acid residues and bases in the DNA or RNA. NF-κB is the name of a family of structurally related eukaryotic transcription factors that regulate processes ranging from immune and inflammatory responses to cell growth and apoptosis. feature of these α helices is the occurrence of Leu residues at every seventh position, forming a straight line along the hydrophobic surface. Although researchers initially thought the Leu residues interdigitated (hence the name "zipper"), we now know that they line up, side by side, as the interacting α helices coil around each other (forming a coiled coil; Fig. 28-15b). Regulatory proteins with leucine zippers often have a separate DNA-binding domain with a high concentration of basic (Lys or Arg) residues that can interact with the negatively charged phosphates of the DNA backbone. Leucine zippers have been found in many eukaryotic proteins and a few bacterial proteins.

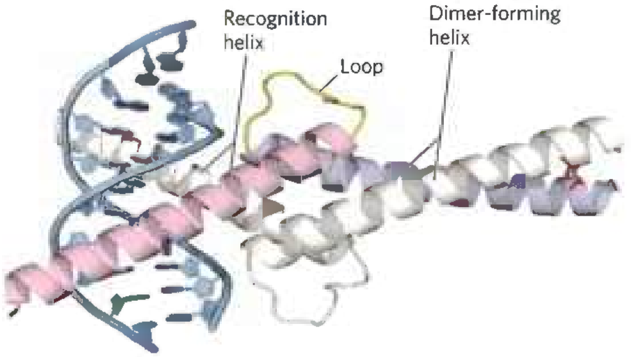
Basic Helix-Loop-Helix Another common structural motif, the **basic helix-loop-helix**, occurs in some eukaryotic regulatory proteins implicated in the control of gene expression during development of multicellular organisms. These proteins share a conserved region of about 50 amino acid residues important in both DNA binding and protein dimerization. This region can form two short, amphipathic α helices linked by a loop of variable length, the helix-loop-helix (distinct from the helix-turn-helix motif associated with DNA binding). The helix-loop-helix motifs of two polypeptides interact to form dimers (**Fig. 28-16**). In these proteins, DNA binding is mediated by an adjacent short amino acid sequence rich in basic residues, similar to the separate DNA-binding region in proteins containing leucine zippers.



Recognition helix
Loop
Dimer-forming helix

FIGURE 28-16 Helix-loop-helix. The human transcription factor Max, bound to its DNA target site. The protein is dimeric; one subunit is colored. The recognition helix is linked via the loop to the dimer-forming helix, which merges with the carboxyl-terminal end of the subunit. Interaction of the carboxyl-terminal helices of the two subunits describes a coiled coil very similar to that of a leucine zipper (see Fig. 28-15b), but with only one pair of interacting Leu residues (side chains at the right) in this example. The overall structure is sometimes called a helix-loop-helix/leucine zipper motif. [Data from PDB ID 1HLO, P. Brownlie et al., *Structure* 5:509, 1997.]

Protein-Protein Interactions in Eukaryotic Regulatory Proteins In eukaryotes, most genes are regulated by activators, and most genes are monocistronic. If a different activator were required for each gene, the number of activators (and genes encoding them) would need to be equivalent to the number of regulated genes. However, in yeast, about 300 transcription factors (many of them activators) are responsible for the regulation of many thousands of genes. Many of the transcription factors regulate the induction of multiple genes, but most genes are subject to regulation by multiple transcription factors. **P4** Appropriate regulation of different genes is accomplished by different combinations of a limited repertoire of transcription factors at each gene, a mechanism referred to as **combinatorial control**.

Combinatorial control is accomplished in part by mixing and matching the variants within a regulatory protein family to form a series of different active protein dimers. Several families of eukaryotic transcription factors have been defined on the basis of close structural similarities. Within each family, dimers can sometimes form between two identical proteins (a homodimer) or between two different members of the family (a heterodimer). A hypothetical family of four different leucine-zipper proteins could thus form up to 10 different dimeric species. In many cases, the different combinations have distinct regulatory and functional properties and regulate different genes. As we shall see, multiple regulatory proteins of this kind function in the regulation of most eukaryotic genes, further contributing to combinatorial control.

In addition to having structural domains devoted to DNA binding and protein dimerization, which direct a particular protein dimer to a particular gene, many regulatory proteins have domains that interact with RNA polymerase, with regulatory RNAs, with unrelated regulatory proteins, or with some combination of the three. At least three types of additional domains for protein-protein interaction have been characterized (primarily in eukaryotes): glutamine-rich, proline-rich, and acidic domains, the names reflecting the amino acid residues that are especially abundant.

Protein-DNA and protein-RNA binding interactions are the basis of the intricate regulatory circuits fundamental to gene function. We now turn to a closer examination of these gene regulatory schemes, first in bacteria, then in eukaryotes.

SUMMARY 28.1 *The Proteins and RNAs of Gene Regulation*

- Transcription is initiated when an RNA polymerase interacts with a site called a promoter. In bacteria, the frequency of transcription initiation is dictated in part by sequence changes within the promoter. For gene products required all the time at a defined level—the products of housekeeping genes—the promoter sequence may be the sole element of regulation. For genes encoding products that are not always needed, regulation is imposed by additional proteins and RNAs.
- Regulation of gene transcription is imposed primarily by three types of proteins: specificity factors, repressors, and activators. Regulatory RNAs also play an important role in regulating the expression of many genes.
- In bacteria, genes that encode products with interdependent functions are often clustered in an operon, a single transcriptional unit. Transcription of the genes is generally blocked by binding of a specific repressor protein at a DNA site called an operator. Dissociation of the repressor from the operator is mediated by a specific small molecule, an inducer.
- Many principles of gene regulation in bacteria were first elucidated in studies of the lactose (*lac*) operon. The Lac repressor dissociates from the *lac* operator when the repressor binds to its inducer, allolactose.
- Regulatory proteins are DNA-binding proteins that recognize specific DNA sequences; most have distinct DNA-binding domains. Within these domains, common structural motifs that bind DNA (and/or RNA) are the helix-turn-helix, zinc finger, homeodomain, and RNA recognition motif.
- Regulatory proteins often contain domains such as the leucine zipper and helix-loop-helix, required for dimerization or other protein-protein interactions, and other motifs required for activation of transcription. Mixing and matching of protein family variants in dimeric transcription factors provides for more efficient and responsive regulation through combinatorial control.

28.2 Regulation of Gene Expression in Bacteria

As in many other areas of biochemical investigation, the study of the regulation of gene expression advanced earlier and faster in bacteria than in other experimental organisms. The examples of bacterial gene regulation presented here are chosen from among scores of well-studied systems, partly for their historical significance, but primarily because they provide a good overview of the range of regulatory mechanisms in bacteria. Many of the principles of bacterial gene regulation are also relevant to understanding gene expression in eukaryotic cells.

We begin by examining the lactose and tryptophan operons; each system has regulatory proteins, but the overall mechanisms of regulation are very different. This is followed by a short discussion of the SOS response in *E. coli*, illustrating how genes scattered throughout the genome can be coordinately regulated. We then describe two bacterial systems of quite different types, illustrating the diversity of gene regulatory mechanisms: regulation of ribosomal protein synthesis at the level of translation, with many of the regulatory proteins binding to RNA (rather than DNA), and regulation of the process of "phase variation" in *Salmonella*, which results from genetic recombination. Finally, we examine some additional examples of posttranscriptional regulation in which the RNA modulates its own function.

The *lac* Operon Undergoes Positive Regulation

The operator-repressor-inducer interactions described earlier for the *lac* operon (Fig. 28-8) provide an intuitively satisfying model for an on/off switch in the regulation of gene expression, but operon regulation is rarely so simple. A bacterium's environment is too complex for its genes to be controlled by one signal. Other factors besides lactose, such as the availability of glucose, affect the expression of the *lac* genes. Glucose, metabolized directly by glycolysis, is the preferred energy source in *E. coli*. Other sugars can serve as the main or sole nutrient, but extra enzymatic steps are required to prepare them for entry into glycolysis, necessitating the synthesis of additional enzymes. Clearly, expressing the genes for proteins that metabolize sugars such as lactose or arabinose is wasteful when glucose is abundant.

What happens to the expression of the *lac* operon when both glucose and lactose are present? A regulatory mechanism known as **catabolite repression** restricts expression of the genes required for catabolism of lactose, arabinose, and other sugars in the presence of glucose, even when these secondary sugars are also present. The effect of glucose is mediated by cAMP, as a coactivator, and an activator protein known as **cAMP receptor protein**, or **CRP** (the protein is sometimes called CAP, for *c*atabolite gene *a*ctivator *p*rotein). CRP is a homodimer (subunit M_r 22,000) with binding sites for DNA and cAMP. Binding is mediated by a helix-turn-helix motif in the protein's DNA-binding domain (**Fig. 28-17**). When glucose is absent, CRP-cAMP binds to a site near the *lac* promoter (**Fig. 28-18**) and stimulates RNA transcription 50-fold. The wild-type *lac* promoter is a relatively weak promoter, diverging from the consensus shown in Figure 28-2. The open complex of RNA polymerase and the promoter (see Fig. 26-6) does not form readily unless CRP-cAMP is present and also bound (Fig. 28-18a, c). CRP-cAMP is therefore a positive regulatory element responsive to glucose levels, whereas the Lac repressor is a negative regulatory element responsive to lactose.

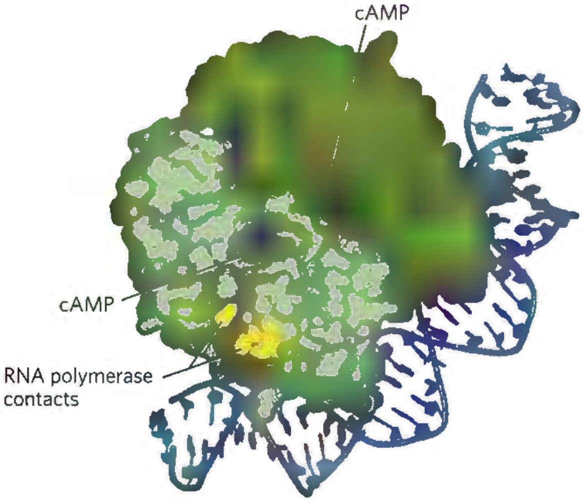


FIGURE 28-17 CRP homodimer with bound cAMP. Note the bending of the DNA around the protein. The region that interacts with RNA polymerase is labeled. [Data from PDB ID 1RUN, G. Parkinson et al., *Nat. Struct. Biol.* 3:837, 1996.]

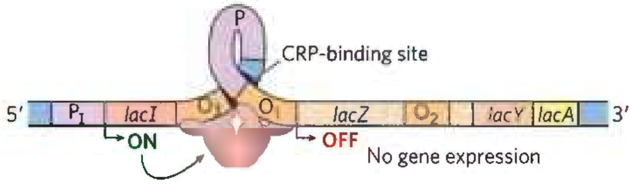
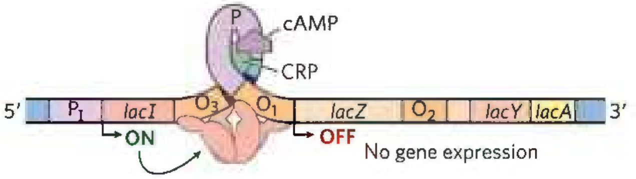
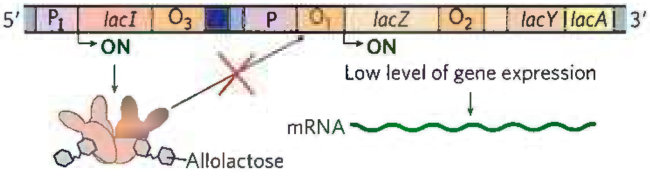
(a) Glucose high, cAMP low, lactose absent



(b) Glucose low, cAMP high, lactose absent



(c) Glucose high, cAMP low, lactose present



(d) Glucose low, cAMP high, lactose present

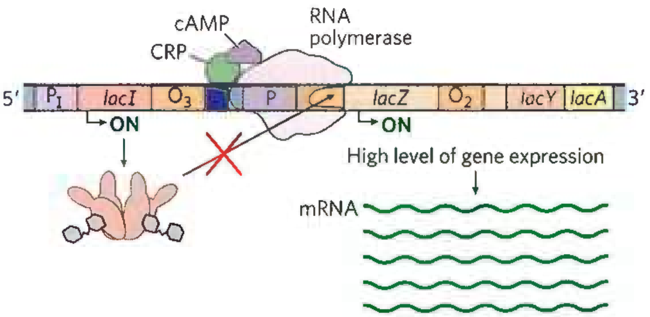


FIGURE 28-18 Positive regulation of the *lac* operon by CRP. The binding site for CRP-cAMP is near the promoter. The combined effects of glucose and lactose availability on *lac* operon expression are shown. When lactose is absent, the repressor binds to the operator and prevents transcription of the *lac* genes. It does not matter whether glucose is (a) present or (b) absent. (c) If lactose is present, the repressor dissociates from the operator. However, if glucose is also available, low cAMP levels prevent CRP-cAMP formation and DNA binding. RNA polymerase may occasionally bind and initiate transcription, resulting in a very low level of *lac* genes transcription. (d) When lactose is present and glucose levels are low, cAMP levels rise. The CRP-cAMP complex forms and facilitates robust binding of RNA polymerase to the *lac* promoter and high levels of transcription.

The two act in concert. CRP-cAMP has little effect on the *lac* operon when the Lac repressor is blocking transcription, and dissociation of the repressor from the *lac* operator has little effect on transcription of the *lac* operon unless CRP-cAMP is present to facilitate transcription. CRP interacts directly with RNA polymerase (at the region shown in Fig. 28-17) through the polymerase's α subunit. Thus, optimal expression of the *lac* operon requires dissociation of the Lac repressor (indicating that lactose is available) and the binding of CRP-cAMP (indicating that glucose is not available).

The effect of glucose on CRP is mediated by the cAMP interaction (Fig. 28-18). CRP binds to DNA most avidly when cAMP concentrations are high. In the presence of glucose, the synthesis of cAMP is inhibited and efflux of cAMP from the cell is stimulated. As [cAMP] declines, CRP binding to DNA declines, thereby decreasing the expression of the *lac* operon.

CRP and cAMP participate in the coordinated regulation of many operons, primarily those that encode enzymes for the metabolism of secondary sugars such as lactose and arabinose. A network of operons with a common regulator is called a **regulon**. This arrangement, which allows coordinated shifts in cellular functions that can require the action of hundreds of genes, is a major theme in the regulated expression of dispersed networks of genes in eukaryotes. Other bacterial regulons include the heat shock gene system that responds to changes in temperature and the genes induced in *E. coli* as part of the SOS response to DNA damage, described later.

Many Genes for Amino Acid Biosynthetic Enzymes Are Regulated by Transcription Attenuation

The 20 common amino acids are required in large amounts for protein synthesis, and *E. coli* can synthesize all of them. The genes for the enzymes needed to synthesize a given amino acid are generally clustered in an operon and are expressed whenever existing supplies of that amino acid are inadequate for cellular requirements. When the amino acid is abundant, the biosynthetic enzymes are not needed and the operon is repressed.

The *E. coli* tryptophan (*trp*) operon (**Fig. 28-19**) includes five genes for the enzymes required to convert chorismate to tryptophan (see Fig. 22-19). Note that two of the enzymes catalyze more than one step in the pathway. The mRNA from the *trp* operon has a half-life of only about 3 min, allowing the cell to respond rapidly to changing needs for this amino acid. The Trp repressor is a homodimer. When tryptophan is abundant, it binds to the Trp repressor, causing a conformational change that permits the repressor to bind to the *trp* operator and inhibit expression of the *trp* operon. The *trp* operator site overlaps the promoter, so binding of the repressor blocks binding of RNA polymerase.

FIGURE 28-19 The *trp* operon. This operon is regulated by two mechanisms: when tryptophan levels are high, (1) the repressor (upper left) binds to its operator and (2) transcription of *trp* mRNA is attenuated (see Fig. 28-20). The biosynthesis of tryptophan by the enzymes encoded in the *trp* operon is diagrammed at the bottom.

Once again, this simple on/off circuit mediated by a repressor is not the entire regulatory story. Different cellular concentrations of tryptophan can vary the rate of synthesis of the biosynthetic enzymes over a 700-fold range. P1 Once repression is lifted and transcription begins, the rate of transcription is fine-tuned to cellular tryptophan requirements by a second regulatory process, called **transcription attenuation**, in which transcription is initiated normally but is abruptly halted *before* the operon genes are transcribed. The frequency with which transcription is attenuated is regulated by the availability of tryptophan and relies on the very close coupling of transcription and translation in bacteria.

The *trp* operon attenuation mechanism uses signals encoded in four sequences within a 162 nucleotide **leader** region at the 5′ end of the mRNA, preceding the initiation codon of the first gene (**Fig. 28-20a**). The leader contains a region known as the **attenuator**, made up of sequences 3 and 4. These sequences base-pair to form a G≡C-rich stem-and-loop structure closely followed by a series of U residues. The attenuator structure acts as a transcription terminator (Fig. 28-20b; see also Fig. 26-7a). Sequence 2 is an alternative complement for sequence 3 (Fig. 28-20c). If sequences 2 and 3 base-pair, the attenuator structure cannot form and transcription continues into the *trp* biosynthetic genes; the loop formed by the pairing of sequences 2 and 3 does not obstruct transcription.

Regulatory sequence 1 is crucial for a tryptophan-sensitive mechanism that determines whether sequence 3 pairs with sequence 2 (allowing transcription to continue) or with sequence 4 (attenuating transcription). Formation of the attenuator stem-and-loop structure depends on events that occur during *translation* of regulatory sequence 1, which encodes a leader peptide (so called because it is encoded by the leader region of the mRNA) of 14 amino acids, two of which are Trp residues. The leader peptide has no other known cellular function; its synthesis is simply an operon regulatory device. This peptide is translated immediately after it is transcribed, by a ribosome that follows closely behind RNA polymerase as transcription proceeds.

When tryptophan concentrations are high, concentrations of charged tryptophan tRNA (Trp-tRNA^{Trp}) are also high. This allows translation to proceed rapidly past the two Trp codons of sequence 1 and into sequence 2, before sequence 3 is synthesized by RNA polymerase. In this situation, sequence 2 is covered by the ribosome and unavailable for pairing to sequence 3 when sequence 3 is synthesized; the attenuator structure (sequences 3 and 4) forms and transcription halts (Fig. 28-20b, top). When tryptophan concentrations are low, however, the ribosome stalls at the two Trp codons in sequence 1, because charged tRNA^{Trp} is less available. Sequence 2 remains free while sequence 3 is synthesized, allowing these two sequences to base-pair and permitting transcription to proceed (Fig. 28-20b, bottom). In this way, the proportion of transcripts that are attenuated declines as tryptophan concentration declines.

Many other amino acid biosynthetic operons use a similar attenuation strategy to fine-tune biosynthetic enzymes to meet the prevailing cellular requirements. The 15 amino acid leader peptide produced by the *phe* operon contains seven Phe residues. The *leu* operon leader peptide has four contiguous Leu residues. The leader peptide for the *his* operon contains seven contiguous His residues. In fact, in the *his* operon and several others, attenuation is sufficiently sensitive to be the *only* regulatory mechanism.

Induction of the SOS Response Requires Destruction of Repressor Proteins

Extensive DNA damage in the bacterial chromosome triggers the induction of nearly 60 genes scattered about the chromosome. P3 The genes involved in the coordinated inducible response, called the SOS response (p. 939), constitute the SOS regulon. Many of the induced genes are involved in DNA repair. The key regulatory proteins are the RecA protein and the LexA repressor.

The LexA repressor (M_r 22,700) inhibits transcription of all the SOS genes (**Fig. 28-21**), and induction of the SOS response requires removal of LexA. This is not a simple dissociation from DNA in response to binding of a small molecule, as in the regulation of the *lac* operon described above. Instead, the LexA repressor is inactivated when it catalyzes its own cleavage at a specific Ala–Gly peptide bond, producing two roughly equal protein fragments. At physiological pH, this autocleavage reaction requires the RecA protein. RecA is not a protease in the classical sense, but its interaction with LexA enables the repressor's self-cleavage reaction. This function of RecA is sometimes called a co-protease activity.

The RecA protein provides the functional link between the biological signal (DNA damage) and induction of the SOS genes. Heavy DNA damage leads to numerous single-strand gaps in the DNA, and only RecA that is bound to single-stranded DNA can facilitate cleavage of the LexA repressor (Fig. 28-21, bottom). Binding of RecA at the gaps eventually activates its co-protease activity, leading to cleavage of the LexA repressor and SOS induction.

During induction of the SOS response in a severely damaged cell, RecA also promotes the autocatalytic cleavage of, and thus inactivates, the repressors that otherwise allow propagation of certain viruses in a dormant lysogenic state within the bacterial host. This provides a remarkable illustration of evolutionary adaptation. These repressors, like LexA, undergo self-cleavage at a specific Ala–Gly peptide bond, so induction of the SOS response permits replication of the virus and lysis of the cell, releasing new viral particles. Thus, the bacteriophage can make a hasty exit from a compromised bacterial host cell.

When tryptophan levels are high, the ribosome quickly translates sequence 1 (open reading frame encoding leader peptide) and blocks sequence 2 before sequence 3 is transcribed. Continued transcription leads to attenuation at the terminator-like attenuator structure formed by sequences 3 and 4.

When tryptophan levels are low, the ribosome pauses at the Trp codons in sequence 1. Formation of the paired structure between sequences 2 and 3 prevents attenuation, because sequence 3 is no longer available to form the attenuator structure with sequence 4. The 2:3 structure, unlike the 3:4 attenuator, does not prevent transcription.

FIGURE 28-20 Transcriptional attenuation in the *trp* operon. Transcription is initiated at the beginning of the 162 nucleotide mRNA leader encoded by a DNA region called *trpL* (see Fig. 28-19). A regulatory mechanism determines whether transcription is attenuated at the end of the leader or continues into the structural genes. (a) The *trp* mRNA leader (*trpL*). The attenuation mechanism in the *trp* operon involves sequences 1 to 4 (highlighted). (b) Sequence 1 encodes a small peptide, the leader peptide, containing two Trp residues (W); it is translated immediately after transcription begins. Sequences 2 and 3 are complementary, as are sequences 3 and 4. The attenuator structure forms by the pairing of sequences 3 and 4 (top). Its structure and function are similar to those of a transcription terminator. Pairing of sequences 2 and 3 (bottom) prevents the attenuator structure from forming. Note that the leader peptide has no other cellular function. Translation of its open reading frame has a purely regulatory role that determines which complementary sequences (2 and 3, or 3 and 4) are paired. (c) Base-pairing schemes for the complementary regions of the *trp* mRNA leader.

FIGURE 28-21 SOS response in *E. coli*. The LexA protein is the repressor in this system, which has an operator site near each gene. Because the *recA* gene is not entirely repressed by the LexA repressor, the normal cell contains about 1,000 RecA monomers. ❶ When DNA is extensively damaged (such as by UV light), DNA replication is halted and the number of single-strand gaps in the DNA increases. ❷ RecA protein binds to this damaged, single-stranded DNA, activating the protein's co-protease activity. ❸ While bound to DNA, the RecA protein facilitates cleavage and inactivation of the LexA repressor. When the repressor is inactivated, the SOS genes, including *recA*, are induced; RecA levels increase 50- to 100-fold.

The destruction of the LexA repressor proteins as part of the response means that LexA must be resynthesized in order to reestablish gene control when the DNA damage is no longer present. P5 The considerable amount of ATP and GTP needed for protein synthesis to maintain SOS regulon repression provides one example of the energetic cost of regulation.

Synthesis of Ribosomal Proteins Is Coordinated with rRNA Synthesis

In bacteria, an increased cellular demand for protein synthesis is met by increasing the number of ribosomes rather than altering the activity of individual ribosomes. In general, the number of ribosomes increases as the cellular growth rate increases. At high growth rates, ribosomes make up approximately 45% of the cell's dry weight. The proportion of cellular resources devoted to making ribosomes is so large, and the function of ribosomes so important, that cells must coordinate the synthesis of the ribosomal components: the ribosomal proteins (r-proteins) and RNAs (rRNAs). P1 This regulation is distinct from the mechanisms described so far: it occurs largely at the level of *translation*.

The 52 genes that encode the r-proteins are distributed across at least 20 operons, each with 1 to 11 genes. Some of these operons also contain the genes for the subunits of DNA primase, RNA polymerase, and protein synthesis elongation factors—reflecting the close coupling of replication, transcription, and protein synthesis during bacterial cell growth.

The r-protein operons are regulated primarily through a translational feedback mechanism. One r-protein encoded by each operon also functions as a **translational repressor**, which binds to the mRNA transcribed from that operon and blocks translation of all the genes the messenger encodes (**Fig. 28-22**). In general, the r-protein that plays the role of repressor also binds directly to an rRNA. Each translational repressor r-protein binds with higher affinity to the appropriate rRNA than to its mRNA, so the mRNA is bound and translation repressed only when the level of the r-protein exceeds that of the rRNA. This ensures that translation of the mRNAs encoding r-proteins is repressed only when synthesis of these r-proteins exceeds that needed to make functional ribosomes. In this way, the rate of r-protein synthesis is kept in balance with rRNA availability.

FIGURE 28-22 Translational feedback in some ribosomal protein operons. The r-proteins that act as translational repressors are shown (red circles). Each translational repressor blocks the translation of all genes in that operon by binding to the indicated site on the mRNA. The operons include the genes that encode the α, β, and β' subunits of RNA polymerase and the elongation factors EF-G and EF-Tu (labeled). The r-proteins of the large (50S) ribosomal subunit are designated L1 to L34; those of the small (30S) subunit are designated S1 to S21.

The mRNA-binding site for the translational repressor is near the translational start site of one of the genes in the operon, often but not always the first gene (Fig. 28-22). In other operons this would affect only that one gene, because in bacterial polycistronic mRNAs, most genes have independent translation signals. In the r-protein operons, however, the translation of one gene depends on the translation of all the others. The translation of multiple genes seems to be blocked by folding of the mRNA into an elaborate three-dimensional structure that is stabilized both by internal base pairing and by binding of the translational repressor protein. When the translational repressor is absent, ribosome binding and translation of one or more of the genes disrupts the folded structure of the mRNA and allows all the genes to be translated.

Because the synthesis of r-proteins is coordinated with the availability of rRNA, the regulation of ribosome production reflects the regulation of rRNA synthesis. In *E. coli*, rRNA synthesis from the seven rRNA operons responds to cellular growth rate and to changes in the availability of crucial nutrients, particularly amino acids. The regulation coordinated with amino acid concentrations is known as the **stringent response** (**Fig. 28-23**). When amino acid concentrations are low, rRNA synthesis is halted. Amino acid starvation leads to the binding of uncharged tRNAs to the ribosomal A site; this triggers a sequence of events that begins with the binding of an enzyme called **stringent factor** (RelA protein) to the ribosome. When bound to the ribosome, stringent factor catalyzes formation of the unusual nucleotide guanosine tetraphosphate (ppGpp); it adds pyrophosphate to the 3′ position of GTP, in the reaction

$$\mathrm{GTP} + \mathrm{ATP} \rightarrow \mathrm{pppGpp} + \mathrm{AMP}$$

Then a phosphohydrolase cleaves off one phosphate to convert some pppGpp to ppGpp. The abrupt rise in pppGpp and ppGpp levels in response to amino acid starvation results in a great reduction in rRNA synthesis, mediated at least in part by the binding of ppGpp to RNA polymerase.

The nucleotides pppGpp and ppGpp, along with cAMP, belong to a class of modified nucleotides that act as cellular second messengers. In *E. coli*, these two nucleotides serve as starvation signals; they cause large changes in cellular metabolism by increasing or decreasing the transcription of hundreds of genes. In eukaryotic cells, similar nucleotide second messengers also have multiple regulatory functions. The coordination of cellular metabolism with cell growth is highly complex, and further regulatory mechanisms undoubtedly remain to be discovered.

The Function of Some mRNAs Is Regulated by Small RNAs in Cis or in Trans

As described throughout this chapter, proteins play an important and well-documented role in regulating gene expression. But RNA also has a crucial role—one that is becoming increasingly recognized as more examples of regulatory RNAs are discovered. Once an mRNA is synthesized, its functions can be controlled by RNA-binding proteins, as seen for the r-protein operons just described, or by an RNA. A separate RNA molecule may bind to the mRNA "in trans" and affect its activity. Alternatively, a portion of the mRNA itself may regulate its own function. When part of a molecule affects the function of another part of the same molecule, it is said to act "in cis."

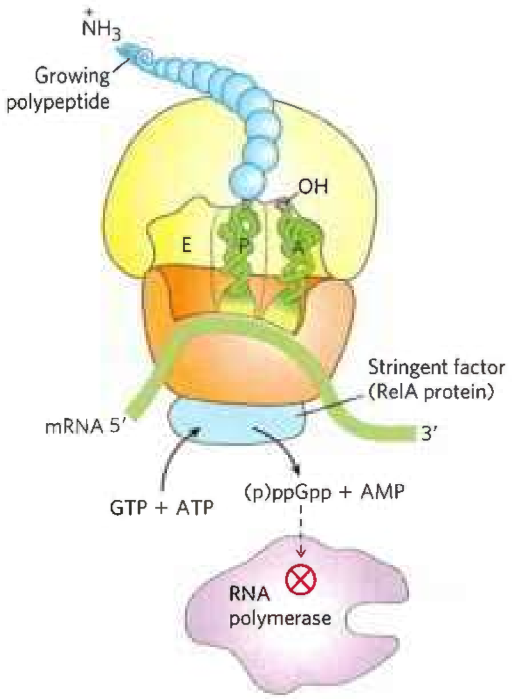

FIGURE 28-23 Stringent response in *E. coli*. This response to amino acid starvation is triggered by binding of an uncharged tRNA in the ribosomal A site. A protein called stringent factor binds to the ribosome and catalyzes the synthesis of pppGpp, which is converted by a phosphohydrolase to ppGpp. The signal ppGpp reduces transcription of some genes and increases transcription of others, in part by binding to the β subunit of RNA polymerase and altering the enzyme's promoter specificity. Synthesis of rRNA is reduced when ppGpp levels increase.

A well-characterized example of RNA regulation in trans is regulation of the mRNA of the gene *rpoS* (*R*NA *po*lymerase *s*igma factor), which encodes σ^S (formerly known as σ^{38}), one of seven *E. coli* sigma factors. The cell uses this specificity factor in certain stress situations, such as when it enters the stationary phase (a state of no growth, necessitated by lack of nutrients) and σ^S is needed to transcribe large numbers of stress response genes. The σ^S mRNA is present at low levels under most conditions but is not translated, because a large hairpin structure upstream of the coding region inhibits ribosome binding (**Fig. 28-24**). **P2** Under certain stress conditions, one or both of two small ncRNAs, DsrA (*d*own*s*tream *r*egion *A*) and RprA (*rpoS* *r*egulator RNA *A*), are induced. Both can pair with one strand of the hairpin in the σ^S mRNA, disrupting the hairpin and thus allowing translation of *rpoS*.

FIGURE 28-24 Regulation of bacterial mRNA function in trans by sRNAs. Several sRNAs (small RNAs)—DsrA, RprA, and OxyS—participate in regulation of the *rpoS* gene. All require the protein Hfq, an RNA chaperone that facilitates RNA-RNA pairing. Hfq has a toroid structure, with a pore in the center. (a) DsrA promotes translation by pairing with one strand of a stem-loop structure that otherwise blocks the ribosome-binding site. RprA (not shown) acts in a similar way. (b) OxyS blocks translation by pairing with the ribosome-binding site. [Information from M. Szymański and J. Barciszewski, *Genome Biol.* 3:reviews0005.1, 2002.]

Another small RNA, OxyS (*ox*idative stress gene *S*), is induced under conditions of oxidative stress and inhibits the translation of *rpoS*, probably by pairing with and blocking the ribosome-binding site on the mRNA. OxyS is expressed as part of a system that responds to a different type of stress (oxidative damage) than does the *rpoS* RNA, and its task is to prevent expression of unneeded repair pathways. DsrA, RprA, and OxyS are all relatively small bacterial RNA molecules (less than 300 nucleotides), designated sRNAs (*s* for small; there are, of course, other "small" RNAs with other designations in eukaryotes). All sRNAs require for their function a protein called Hfq, an RNA chaperone that facilitates RNA-RNA pairing. The known bacterial genes regulated in this way are few in number, just a few dozen in a typical bacterial species. However, these examples provide good model systems for understanding patterns present in the more complex and numerous examples of RNA-mediated regulation in eukaryotes.

Regulation in cis involves a class of RNA structures known as **riboswitches**. As described in Box 26-4, aptamers are RNA molecules, generated in vitro, that are capable of specific binding to a particular ligand. As one might expect, such ligand-binding RNA domains are also present in nature—in riboswitches—in a significant number of bacterial mRNAs (and even in some eukaryotic mRNAs). These natural aptamers are structured domains found in untranslated regions at the 5′ ends of certain bacterial mRNAs. Some riboswitches also regulate the transcription of certain noncoding RNAs. Binding of an mRNA's riboswitch to its appropriate ligand results in a conformational change in the mRNA, and transcription is inhibited by stabilization of a premature transcription termination structure, or translation is inhibited (in cis) by occlusion of the ribosome-binding site (**Fig. 28-25**). In most cases, the riboswitch acts in a kind of feedback loop. Most genes

FIGURE 28-25 Regulation of bacterial mRNA function in cis by riboswitches. The known modes of action are illustrated by several different riboswitches, based on a widespread natural aptamer that binds thiamine pyrophosphate. TPP binding to the aptamer leads to a conformational change that produces the varied results illustrated in (a), (b), and (c) in several different systems in which the aptamer is utilized. [Information from W. C. Winkler and R. R. Breaker, *Annu. Rev. Microbiol.* 59:487, 2005.]

regulated in this way are involved in the synthesis or transport of the ligand that is bound by the riboswitch; thus, when the ligand is present in high concentrations, the riboswitch inhibits expression of the genes needed to replenish this ligand.

Each riboswitch binds only one ligand. Distinct riboswitches have been detected that respond to more than a dozen different ligands, including thiamine pyrophosphate (TPP, vitamin B_1), cobalamin (vitamin B_{12}), flavin mononucleotide, lysine, *S*-adenosylmethionine (adoMet), purines, *N*-acetylglucosamine 6-phosphate, glycine, and some metal cations such as Mn^{2+}. It is likely that many more remain to be discovered. The riboswitch that responds to TPP seems to be the most widespread; it is found in many bacteria, fungi, and some plants. The bacterial TPP riboswitch inhibits translation in some species and induces premature transcription termination in others (Fig. 28-25). The eukaryotic TPP riboswitch is found in the introns of certain genes and modulates the alternative splicing of those genes. It is not yet clear how common riboswitches are. However, estimates suggest that more than 4% of the genes of *Bacillus subtilis* are regulated by riboswitches.

Most of the riboswitches described to date, including the one that responds to adoMet, have been found only in bacteria. A drug that bound to and activated the adoMet riboswitch would shut down the genes encoding the enzymes that synthesize and transport adoMet, effectively starving the bacterial cells of this essential cofactor. Drugs of this type are being sought for use as a new class of antibiotics. ■

The pace of discovery of functional RNAs shows no signs of abating and continues to bolster the hypothesis that RNA played a special role in the evolution of life (Chapter 26). The sRNAs and riboswitches, like ribozymes and ribosomes, may be vestiges of an RNA world obscured by time but persisting as a rich array of biological devices still functioning in the biosphere. The laboratory selection of aptamers and ribozymes with novel ligand-binding and enzymatic functions tells us that the RNA-based activities necessary for a viable RNA world are possible. Discovery of many of the same RNA functions in living organisms tells us that key components for RNA-based metabolism do exist. For example, the natural aptamers of riboswitches may be derived from RNAs that, billions of years ago, bound to cofactors needed to promote the enzymatic processes required for metabolism in the RNA world.

Some Genes Are Regulated by Genetic Recombination

We turn now to another mode of bacterial gene regulation, at the level of DNA rearrangement—recombination. *Salmonella typhimurium*, which inhabits the mammalian intestine, moves by rotating the flagella on its cell surface (**Fig. 28-26**). The many copies of the protein flagellin (M_r 53,000) that make up the flagella are prominent targets of mammalian immune systems. But *Salmonella* cells have a mechanism that evades the immune response: they switch between two distinct flagellin proteins (FljB and FliC) roughly once every 1,000 generations, using a process called **phase variation**.

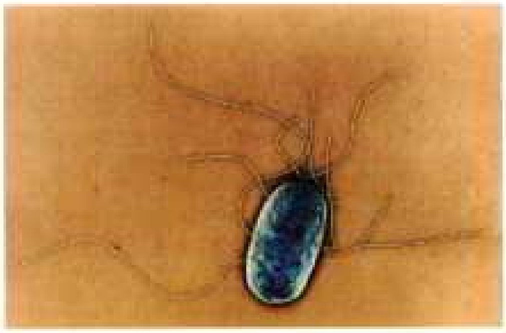

FIGURE 28-26 ***Salmonella typhimurium.*** The appendages emanating from the cell are flagella. [Eye of Science/Science Source.]

The switch is accomplished by periodic inversion of a segment of DNA containing the promoter for a flagellin gene. The inversion is a site-specific recombination reaction (see Fig. 25-37) mediated by the Hin recombinase at specific 14 bp sequences (*hix* sequences) at each end of the DNA segment. When the DNA segment is in one orientation, the gene for FljB flagellin and the gene encoding a repressor, FljA, are expressed (**Fig. 28-27a**); the repressor shuts down expression of the gene for FliC flagellin. When the DNA segment is inverted (Fig. 28-27b), the *fljA* and *fljB* genes are no longer transcribed, and the *fliC* gene is induced as the repressor becomes depleted. The Hin recombinase, encoded by the *hin* gene in the DNA segment that undergoes inversion, is expressed when the DNA segment is in either orientation, so the cell can always switch from one state to the other.

This type of regulatory mechanism has the advantage of being absolute: gene expression is impossible when the gene is physically separated from its promoter (note the position of the *fljB* promoter in Fig. 28-27b). An absolute on/off switch may be important in this system (even though it affects only one of the two flagellin genes) because a flagellum with just one copy of the wrong flagellin might be vulnerable to host antibodies against that protein. The *Salmonella* system is by no means unique. Similar regulatory systems occur in some other bacteria and in some bacteriophages, and recombination systems with similar functions have been found in eukaryotes (**Table 28-1**). Gene regulation by DNA rearrangements that move genes and/or promoters is particularly common in pathogens that benefit by changing their host range or by changing their surface proteins, thereby staying ahead of host immune systems.

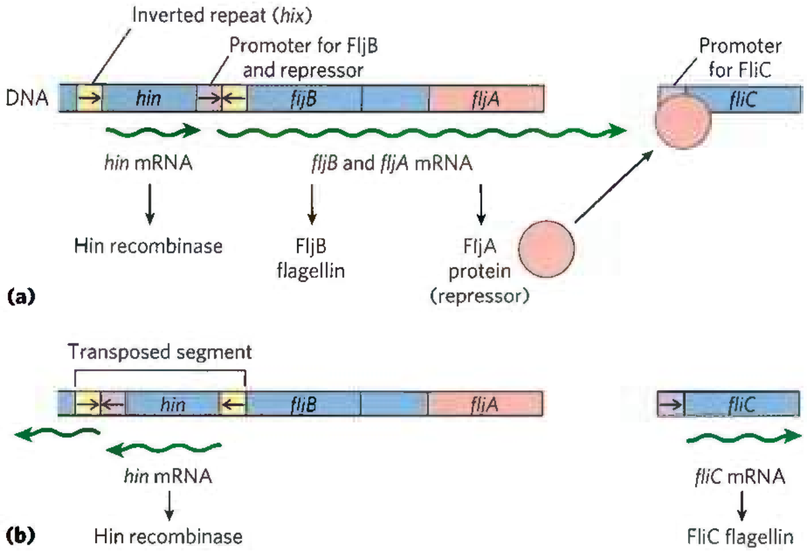

FIGURE 28-27 Regulation of flagellin genes in *Salmonella*: phase variation. The products of genes *fliC* and *fljB* are different flagellins. The *hin* gene encodes the recombinase that catalyzes inversion of the DNA segment containing the *fljB* promoter and the *hin* gene. The recombination sites (inverted repeats) are called *hix*. (a) In one orientation, *fljB* is expressed along with a repressor protein (product of the *fljA* gene) that represses transcription of the *fliC* gene. (b) In the opposite orientation, only the *fliC* gene is expressed; the *fljA* and *fljB* genes cannot be transcribed. The interconversion between these two states, known as phase variation, also requires two other nonspecific DNA-binding proteins (not shown), HU and FIS.

TABLE 28-1 Examples of Gene Regulation by Recombination

System	Recombinase/recombination site	Type of recombination	Function
Phase variation (*Salmonella*)	Hin/*hix*	Site-specific	Alternative expression of two flagellin genes allows evasion of host immune response.
Host range (bacteriophage μ)	Gin/*gix*	Site-specific	Alternative expression of two sets of tail fiber genes affects host range.
Mating-type switch (yeast)	HO endonuclease, RAD52 protein, other proteins/*MAT*	Nonreciprocal gene conversion[a]	Alternative expression of two mating types of yeast, a and α, creates cells of different mating types that can mate and undergo meiosis.
Antigenic variation (trypanosomes)[b]	Varies	Nonreciprocal gene conversion[a]	Successive expression of different genes encoding the variable surface glycoproteins (VSGs) allows evasion of host immune response.

[a] In nonreciprocal gene conversion (a class of recombination events not discussed in Chapter 25), genetic information is moved from one part of the genome (where it is silent) to another (where it is expressed). The reaction is similar to replicative transposition (see Fig. 25-41).

[b] Trypanosomes cause African sleeping sickness and other diseases (see Box 6-1). The outer surface of a trypanosome is made up of multiple copies of a single VSG, the major surface antigen. A cell can change surface antigens to more than 100 different forms, precluding an effective defense by the host immune system.

SUMMARY 28.2 *Regulation of Gene Expression in Bacteria*

- In addition to repression by the Lac repressor, the *E. coli lac* operon undergoes positive regulation by the cAMP receptor protein (CRP). When [glucose] is low, [cAMP] is high and CRP-cAMP binds to a specific site on the DNA, stimulating transcription of the *lac* operon and production of lactose-metabolizing enzymes. The presence of glucose depresses [cAMP], decreasing expression of *lac* and other genes involved in metabolism of secondary sugars. A group of coordinately regulated operons is referred to as a regulon.
- Operons that produce the enzymes of amino acid synthesis have a regulatory circuit called attenuation, which uses a transcription termination site, called the attenuator, in the mRNA. Formation of the attenuator is modulated by a mechanism that couples transcription and translation while responding to small changes in amino acid concentration.
- In the SOS system, multiple unlinked genes repressed by a single repressor are induced simultaneously when DNA damage triggers RecA protein–facilitated autocatalytic proteolysis of the repressor.
- In the synthesis of ribosomal proteins, one protein in each r-protein operon acts as a translational repressor. The mRNA is bound by the repressor, and translation is blocked only when the r-protein is present in excess of available rRNA.
- Posttranscriptional regulation of some mRNAs is mediated by sRNAs that act in trans or by riboswitches, part of the mRNA structure itself, that act in cis.

- Some genes are regulated by genetic recombination processes that move promoters relative to the genes being regulated. Regulation can also take place at the level of translation.

28.3 Regulation of Gene Expression in Eukaryotes

Initiation of transcription is a crucial regulation point for gene expression in all organisms. Although eukaryotes and bacteria use some of the same regulatory mechanisms, the regulation of transcription in the two systems is fundamentally different.

P4 We can define a transcriptional ground state as the inherent activity of promoters and transcriptional machinery in vivo in the absence of regulatory sequences. In bacteria, RNA polymerase generally has access to every promoter and can bind and initiate transcription at some level of efficiency in the absence of activators or repressors. In eukaryotes, however, strong promoters are generally inactive in vivo in the absence of regulatory proteins. This fundamental difference gives rise to at least five important features that distinguish the regulation of gene expression at eukaryotic promoters from that observed in bacteria.

First, access to eukaryotic promoters is restricted by the structure of chromatin, and activation of transcription is associated with many changes in chromatin structure in the transcribed region. Second, although eukaryotic cells have both positive and negative regulatory mechanisms, positive mechanisms are more prominent. Almost every eukaryotic gene requires activation to be transcribed. Third, regulatory mechanisms involving lncRNAs are more common in eukaryotic transcriptional regulation. Fourth, eukaryotic cells have larger, more complex multimeric regulatory proteins than do bacteria. Finally, transcription in the eukaryotic nucleus is separated from translation in the cytoplasm in both space and time.

The complexity of regulatory circuits in eukaryotic cells is extraordinary, as is evident from the following discussion. The section ends with an illustrated description of one of the most elaborate circuits: the regulatory cascade that controls development in fruit flies.

Transcriptionally Active Chromatin Is Structurally Distinct from Inactive Chromatin

The effects of chromosome structure on gene regulation in eukaryotes have no clear parallel in bacteria. In the eukaryotic cell cycle, interphase chromosomes appear, at first viewing, to be dispersed and amorphous (see Fig. 24-22). Nevertheless, several forms of chromatin can be found along these chromosomes. About 10% of the chromatin in a typical eukaryotic cell is in a more condensed form than the rest of the chromatin. This form, **heterochromatin**, is transcriptionally inactive. Heterochromatin is generally associated with particular chromosome structures—the centromeres, for example. The remaining, less condensed chromatin is called **euchromatin**.

Transcription of a eukaryotic gene is strongly repressed when its DNA is condensed within heterochromatin. Some, but not all, of the euchromatin is transcriptionally active. Transcriptionally active chromosomal regions are distinguished from heterochromatin in at least three ways: the positioning of nucleosomes, the presence of histone variants, and the covalent modification of nucleosomes. These transcription-associated structural changes in chromatin are collectively called **chromatin remodeling**. The remodeling employs a set of enzymes that promote these changes (**Table 28-2**).

Four known families of chromatin remodeling complexes, distinguished by their structural features, act directly to alter nucleosome composition in transcribed regions. They may unwrap, translocate, remove, or exchange nucleosomes on the DNA, hydrolyzing ATP in the process (Table 28-2; see the table footnote for an explanation of the abbreviated names of enzyme complexes described here). In some cases, the enzymes catalyze the exchange of pairs of histones within nucleosomes to alter nucleosome composition. The multitude of different complexes are specialized to function at particular genes or chromosomal regions. There are two related complexes in the **SWI/SNF** family in all eukaryotic cells, both of which remodel chromatin so that nucleosomes are ejected from the DNA near transcription start sites. They appear to be involved in a dynamic cycle to allow replacement of nucleosomes with transcription factors (**Fig. 28-28**). The two distinct complexes generally function at different sets of genes. Most of the **ISWI** family complexes optimize nucleosome spacing to allow chromatin assembly and transcriptional silencing. There are generally 9 or 10 different **CHD** family complexes in eukaryotic cells, separated into three subfamilies. The different family members have specialized roles, either ejecting nucleosomes to activate transcription or assembling chromatin to repress transcription. The **INO80** family complexes have a variety of roles in remodeling chromatin for transcriptional activation and DNA repair. One family member, SWR1, promotes subunit exchange in nucleosomes to introduce histone variants such as H2AZ (see Box 24-1), found in transcriptionally active regions.

The covalent modification of histones is altered dramatically within transcriptionally active chromatin. The core histones of nucleosome particles (H2A, H2B, H3, H4; see Fig. 24-24) are modified by methylation of Lys or Arg residues, phosphorylation of Ser or Thr residues, acetylation (see below), ubiquitination (see Fig. 27-47), or SUMOylation (SUMOs are *s*mall *u*biquitin-like *mo*difiers). Each of the core histones has two distinct structural domains. A central domain is involved in histone-histone interaction and the wrapping of DNA

TABLE 28-2 Some Enzyme Complexes That Catalyze Chromatin Structural Changes Associated with Transcription

Enzyme complex[a]	Oligomeric structure (number of polypeptides)	Source	Activities
Histone movement, replacement, or editing, requiring ATP			
SWI/SNF family	8–17, $M_r > 10^6$	Eukaryotes	Nucleosome remodeling; transcriptional activation
ISWI family	2–4	Eukaryotes	Nucleosome remodeling; transcriptional repression; transcriptional activation in some cases
CHD family	1–10	Eukaryotes	Nucleosome remodeling; nucleosome ejection for transcriptional activation; some have repressive roles
INO80 family	>10	Eukaryotes	Nucleosome remodeling; transcriptional activation; family member SWR1 engages in replacement of H2A-H2B with H2AZ-H2B
Histone modification			
GCN5-ADA2-ADA3	3	Yeast	GCN5 has type A HAT activity
SAGA/PCAF	>20	Eukaryotes	Includes GCN5-ADA2-ADA3; acetylates residues in H3, H2B, H2AZ
NuA4	≥12	Eukaryotes	EsaI component has HAT activity; acetylates H4, H2A, and H2AZ
Histone chaperones not requiring ATP			
HIRA	1	Eukaryotes	Deposition of H3.3 during transcription

[a] The abbreviations for eukaryotic genes and proteins are often more confusing or obscure than those used for bacteria. SWI (*sw*itching) was discovered as a protein required for expression of certain genes involved in mating-type switching in yeast, and SNF (*s*ucrose *n*on*f*ermenting) as a factor for expression of the yeast gene for sucrase. Subsequent studies revealed multiple SWI and SNF proteins that act in a complex. The SWI/SNF complex has a role in expression of a wide range of genes and has been found in many eukaryotes, including humans. ISWI is *i*mitation *SWI*. CHD is *c*hromodomain, *h*elicase, *D*NA binding; INO80 is *ino*sitol-requiring *80*; and SWR1 is *SW*i2/Snf2-*r*elated ATPase 1. The complex of GCN5 (*g*eneral *c*ontrol *n*onderepressible) and ADA (*a*lteration/*d*eficiency in *a*ctivation) proteins was discovered during investigation of the regulation of nitrogen metabolism genes in yeast. These proteins can be part of the larger SAGA (SPF, ADA2,3, GCN5, *a*cetyltransferase) complex in yeasts. The equivalent of SAGA in humans is PCAF (*p*300/*C*BP-*a*ssociated *f*actor). NuA4 is *nu*cleosome *a*cetyltransferase of H*4*; ESA1 is *e*ssential *S*AS2-related *a*cetyltransferase; HIRA is *hi*stone *r*egulator *A*

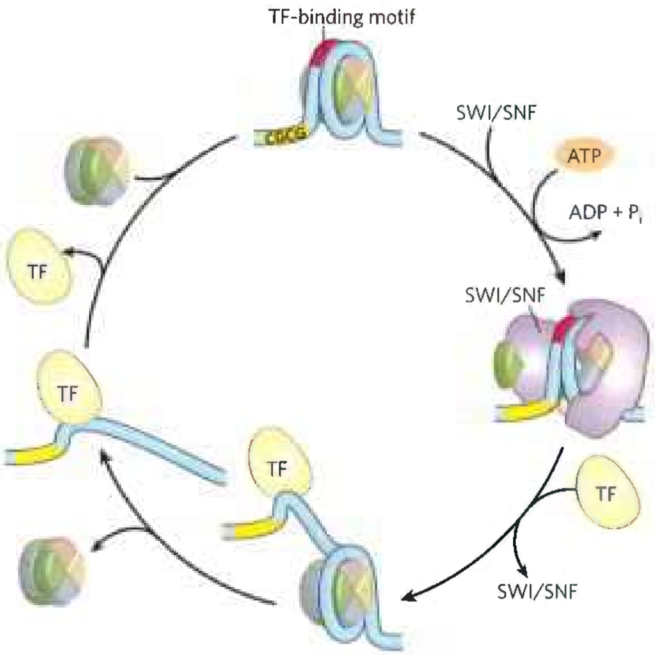

FIGURE 28-28 Nucleosome ejection by a SWI/SNF remodeler. The SWI/SNF enzyme engulfs the nucleosome, interacting with short CGCG sequences nearby. With the aid of ATP hydrolysis, the DNA is partially separated from the nucleosome, exposing a site for transcription factor (TF) binding. After the transcription factor is bound, the nucleosome is ejected. When transcription is no longer needed, the nucleosome can again replace the transcription factor or factors, completing the cycle. [Information from S. Brahma and S. Henikoff, *Trends Biochem. Sci.* 45:13, 2020.]

around the nucleosome. A lysine-rich amino-terminal domain is generally positioned near the exterior of the assembled nucleosome particle; the covalent modifications occur at specific residues concentrated in this amino-terminal domain. The patterns of modification have led some researchers to propose the existence of a histone code, in which modification patterns are recognized by enzymes that alter the structure of chromatin. Indeed, some of the modifications are essential for interactions with proteins that play key roles in transcription.

The acetylation and methylation of histones figure prominently in the processes that activate chromatin for transcription. During transcription, histone H3 in nucleosomes is methylated (by specific histone methylases) at Lys^4 near the 5′ end of the coding region and at Lys^{36} within the coding region. These methylations enable the binding of **histone acetyltransferases (HATs)**, enzymes that acetylate particular Lys residues. Cytosolic (type B) HATs acetylate newly synthesized histones before the histones are imported into the nucleus. The subsequent assembly of the histones into chromatin after replication is facilitated by histone chaperones: CAF1 for H3 and H4 (see Box 24-1), and NAP1 for H2A and H2B.

Where chromatin is being activated for transcription, the nucleosomal histones are further acetylated by nuclear (type A) HATs. The acetylation of multiple Lys residues in the amino-terminal domains of histones

H3 and H4 can reduce the affinity of the entire nucleosome for DNA. Acetylation of particular Lys residues is critical for the interaction of nucleosomes with other proteins.

When transcription of a gene is no longer required, the extent of methylation and acetylation of nucleosomes in that vicinity is reduced as part of a general gene-silencing process that restores the chromatin to a transcriptionally inactive state. There are two known classes of demethylases. One class, called LSD (*l*ysine-*s*pecific histone *d*emethylases), first converts the CH_3—N linkage to an imine (CH_2=N) linkage, followed by hydrolysis to generate formaldehyde and the demethylated lysine. The other class of demethylases contains JmjC (Jumonji-C) domains, first hydroxylating the methyl group, which is again subsequently removed as formaldehyde. More than 20 JmjC domain–containing histone demethylases are encoded by mammalian genomes. They are part of the same α-ketoglutarate-dependent hydroxylase enzyme family that includes the enzyme that hydroxylates proline residues in collagen (see Box 4-2). These enzymes are strongly inhibited by 2-hydroxyglutarate, an unusual metabolite produced in abundance by a mutated form of isocitrate dehydrogenase that is common in human cancers (see Fig. 16-20). Within the tumors, the high levels of 2-hydroxyglutarate produce global changes in gene expression. ■

Histone acetylation is reduced by the action of **histone deacetylases (HDACs)**. The deacetylases include SIRT1, SIRT2, SIRT6, and SIRT7, which are NAD^+-dependent enzymes in the sirtuin family (SIRT1–7 in mammals). These enzymes deacetylate specific Lys residues in histones and other, cytoplasmic targets. In addition to the removal of certain acetyl groups, new covalent modification of histones marks chromatin as transcriptionally inactive. For example, Lys^9 of histone H3 is often methylated in heterochromatin.

The net effect of chromatin remodeling in the context of transcription is to make a segment of the chromosome more accessible and to "label" (chemically modify) it so as to facilitate the binding and activity of transcription factors that regulate expression of the gene or genes in that region.

Most Eukaryotic Promoters Are Positively Regulated

As already noted, eukaryotic RNA polymerases have little or no intrinsic affinity for their promoters. P4 The default state of eukaryotic genes is "off," and initiation of transcription is almost always dependent on the action of multiple activator proteins. One important reason for the apparent predominance of positive regulation seems obvious: the storage of DNA within chromatin effectively renders most promoters inaccessible, so genes are silent in the absence of other regulation. The structure of chromatin affects access to some promoters more than others, but repressors that bind to DNA so as to preclude access of RNA polymerase (negative regulation) would often be simply redundant. Other factors must be at play in the use of positive regulation, and speculation generally centers around two: the large size of eukaryotic genomes and the greater efficiency of positive regulation.

First, nonspecific DNA binding of regulatory proteins becomes a more important problem in the much larger genomes of higher eukaryotes. And the chance that a single specific binding sequence will occur randomly at an inappropriate site also increases with genome size. Combinatorial control thus becomes important in a large genome (**Fig. 28-29**). Specificity for transcriptional activation can be improved if each of several positive regulatory proteins must bind specific DNA sequences to activate a gene. The average number of regulatory sites for a gene in a multicellular organism is six, and genes that are regulated by a dozen such sites are common. The requirement for binding of several positive regulatory proteins to specific DNA sequences vastly reduces the probability of the random occurrence of a functional juxtaposition of all the necessary binding sites. This requirement also reduces the number of regulatory proteins that must be encoded by a genome to regulate all of its genes (Fig. 28-28). Thus, a new regulator is not needed for every gene, although regulation is complex enough in higher eukaryotes that regulatory proteins may represent 5% to 10% of all protein-coding genes.

In principle, a similar combinatorial strategy could be used by multiple negative regulatory elements, but this brings us to the second reason for the use of positive regulation: it is simply more efficient. If the ~20,000 genes in the human genome were negatively regulated, each cell would have to synthesize, at all times, all of the different repressors in concentrations sufficient to permit specific binding to each "unwanted" gene. In positive regulation, most of the genes are usually inactive (that is, RNA polymerases do not bind to the promoters) and the cell synthesizes only the activator proteins needed to promote transcription of the subset of genes required in the cell at that time.

These arguments notwithstanding, there are examples of negative regulation in eukaryotes, from yeasts to humans, as we shall see. Some of that negative regulation involves lncRNAs, which are more economical to synthesize than repressor proteins.

DNA-Binding Activators and Coactivators Facilitate Assembly of the Basal Transcription Factors

To continue our exploration of the regulation of gene expression in eukaryotes, we return to the interactions between promoters and RNA polymerase II (Pol II), the enzyme responsible for the synthesis of eukaryotic

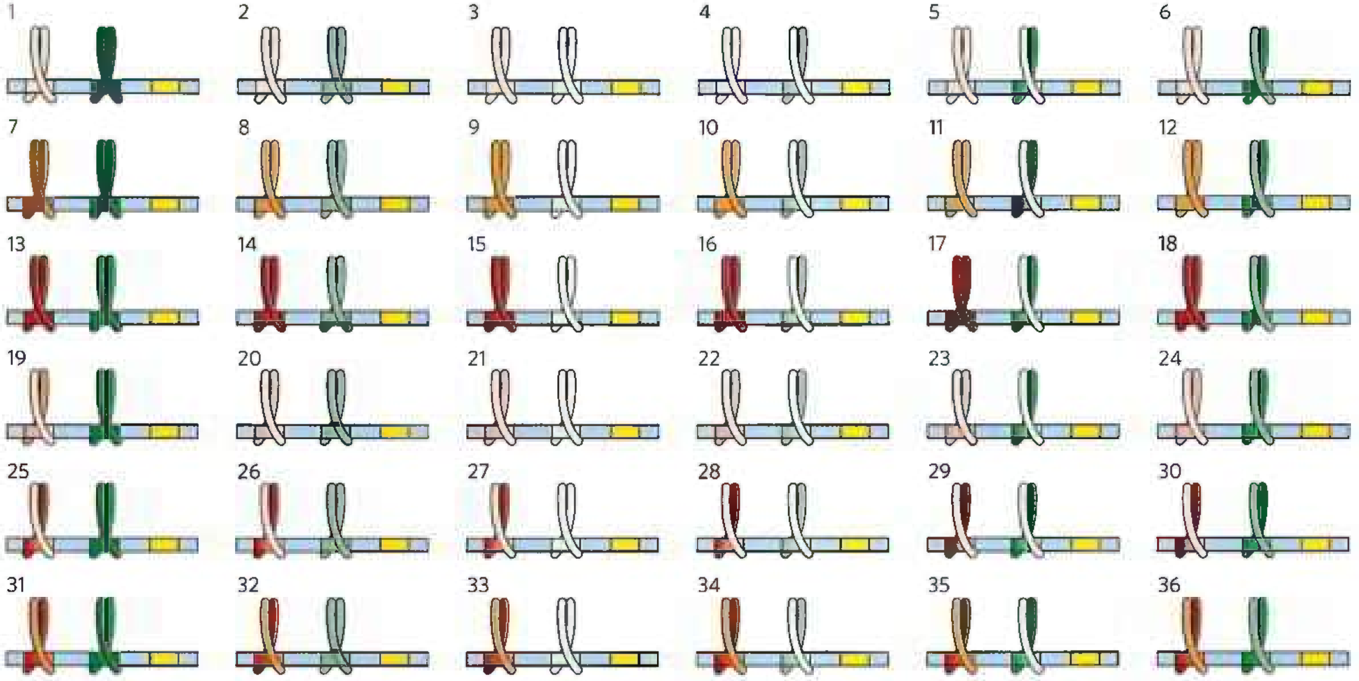

FIGURE 28-29 The advantages of combinatorial control. Combinatorial control allows specific regulation of many genes using a limited repertoire of regulatory proteins. Consider the possibilities inherent in regulation by two different families of leucine zipper proteins (red and green). If each regulatory gene family had three members (as shown here, in dark, medium, and light shades, each binding to a different DNA sequence) that could freely form either homo- or heterodimers, there would be six possible dimeric species in each family and each dimer would recognize a different bipartite regulatory DNA sequence. If a gene had a regulatory site for each protein family, 36 different regulatory combinations would be possible, using just the six proteins from these two families. With six or more sites used in the regulation of a typical eukaryotic gene, the number of possible variants is much greater than this example suggests.

mRNAs. Although many (but not all) Pol II promoters include the TATA box and Inr (initiator) sequences, with their standard spacing (see Fig. 26-8), they vary greatly in both the number and the location of additional sequences required for the regulation of transcription.

The additional regulatory sequences, generally bound by transcription activators, are usually called **enhancers** in higher eukaryotes and **upstream activator sequences (UASs)** in yeast. A typical enhancer may be found hundreds or even thousands of base pairs upstream from the transcription start site, or may even be downstream, within the gene itself. When bound by the appropriate regulatory proteins, an enhancer increases transcription at nearby promoters regardless of its orientation in the DNA. The UASs of yeast function in a similar way, although generally they must be positioned upstream and within a few hundred base pairs of the transcription start site.

Successful binding of the active Pol II holoenzyme at one of its promoters usually requires the combined action of proteins of five types: (1) **transcription activators**, which bind to enhancers or UASs and facilitate transcription; (2) **architectural regulators**, which facilitate DNA looping; (3) **chromatin modification and remodeling proteins**, described above; (4) **coactivators**; and (5) **basal transcription factors**, also called general transcription factors (see Fig. 26-9, Table 26-2), required at most Pol II promoters (**Fig. 28-30**). The coactivators are required for essential communication between activators and the complex composed of Pol II and the basal transcription factors. Coactivators also play a direct role in assembly of the **preinitiation complex (PIC)**. Furthermore, a variety of repressor proteins can interfere with communication between Pol II and the activators, resulting in repression of transcription (Fig. 28-30b). Here we focus on the protein complexes shown in Figure 28-30 and how they interact to activate transcription.

Transcription Activators The requirements for activators vary greatly from one promoter to another. A few are known to activate transcription at hundreds of promoters, whereas others are specific for a few promoters. Many activators are sensitive to the binding of signal molecules, providing the capacity to activate or deactivate transcription in response to a changing cellular environment. Some enhancers bound by activators are quite distant from the promoter's TATA box. Multiple enhancers (often six or more) are bound by a similar number of activators for a typical gene, providing combinatorial control and response to multiple signals.

Some transcription activators can bind to both DNA and RNA, and their function is affected by one or more

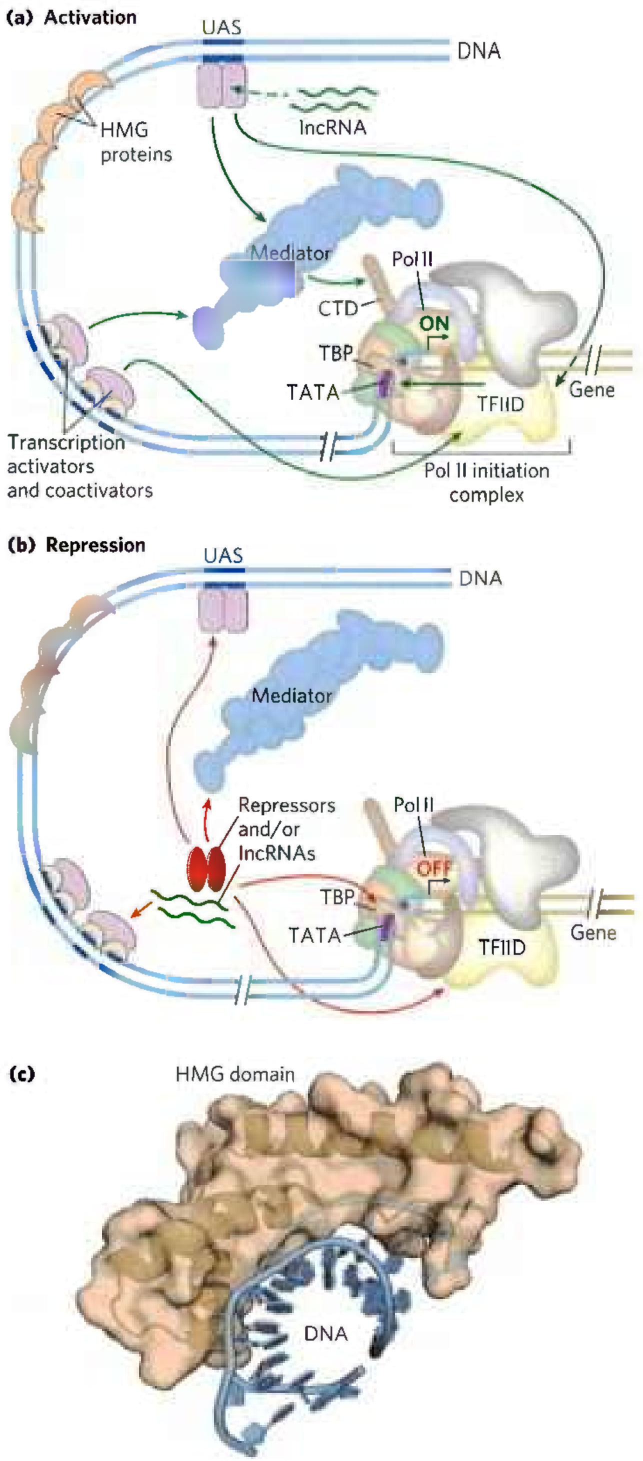

FIGURE 28-30 Eukaryotic promoters and regulatory proteins. RNA polymerase II and its associated basal (general) transcription factors form a preinitiation complex at the TATA box and Inr site of the cognate promoters, a process facilitated by transcription activators, acting through coactivators (Mediator, TFIID, or both). (a) A composite promoter with typical sequence elements and protein complexes found in both yeast and higher eukaryotes. The carboxyl-terminal domain (CTD) of Pol II (see Fig. 26-9) is an important point of interaction with Mediator and other protein complexes. Histone modification enzymes (not shown) catalyze methylation and acetylation; remodeling enzymes alter the content and placement of nucleosomes. The transcription activators have distinct DNA-binding domains and activation domains. In some cases, their function is affected by interaction with lncRNAs. Arrows indicate common modes of interaction often required for the activation of transcription. The HMG proteins are a common type of architectural regulator (see Fig. 28-5), allowing the looping of the DNA required to bring together system components bound at distant binding sites. (b) Eukaryotic transcriptional repressors function through a range of mechanisms. Some bind directly to DNA, displacing a protein complex required for activation (not shown); many others interact with various parts of the transcription or activation protein complexes to prevent activation. Possible points of interaction are indicated with arrows. (c) The structure of an HMG protein complex with DNA shows how HMG proteins facilitate DNA looping. The binding is relatively nonspecific, although DNA sequence preferences have been identified for many HMG proteins. Shown here is the HMG domain of the protein HMG-D of *Drosophila*, bound to DNA. [(c) Data from PDB ID 1QRV, F. V. Murphy IV et al., *EMBO J.* 18:6610, 1999.]

lncRNAs. The protein NF-κB, for example (Fig. 28-14), activates transcription of many genes involved in the immune response and cytokine production. It can bind to a DNA enhancer site or, alternatively, to an lncRNA called *lethe*, named after the river of forgetfulness in Greek mythology. The lncRNA reduces transcription of genes controlled by NF-κB.

Architectural Regulators How do activators function at a distance? The answer in most cases seems to be that, as indicated earlier, the intervening DNA is looped so that the various protein complexes can interact directly. The looping is promoted by architectural regulators that are abundant in chromatin and bind to DNA with limited specificity. Most prominently, the **high mobility group (HMG)** proteins (Fig. 28-29c; "high mobility" refers to their electrophoretic mobility in polyacrylamide gels) play an important structural role in chromatin remodeling and transcriptional activation.

Coactivator Protein Complexes Most transcription requires the presence of additional protein complexes. Some major regulatory protein complexes that interact with Pol II have been defined both genetically and biochemically. These coactivator complexes act as intermediaries between the transcription activators and the Pol II complex.

Mediator, a complex consisting of 25 (yeast) to 30 (human) polypeptides, is a major eukaryotic coactivator (Fig. 28-30). Many of the 25 core polypeptides are highly conserved from fungi to humans. A subcomplex of four subunits has a kinase role, interacting transiently with the remainder of the Mediator complex, and may dissociate prior to transcription initiation. Mediator binds tightly to the carboxyl-terminal domain (CTD) of the largest subunit of Pol II. The Mediator complex is required for both basal and regulated transcription at many promoters used by Pol II, and it also stimulates phosphorylation of the CTD by TFIIH (a basal transcription factor). Transcription activators interact with one or more components of the Mediator complex, with the precise interaction sites differing from one activator to another. Coactivator complexes function at or near the promoter's TATA box.

Additional coactivators, functioning with one or a few genes, have also been described. Some of these operate in conjunction with Mediator, and some may act in systems that do not employ Mediator.

TATA-Binding Protein and Basal Transcription Factors The first component to bind in the assembly of a preinitiation complex (PIC) at the TATA box of a typical Pol II promoter is the **TATA-binding protein (TBP)**. At promoters lacking a TATA box, TBP is usually delivered as part of a larger complex (13 to 14 subunits) called TFIID. The complete complex also includes the basal transcription factors TFIIB, TFIIE, TFIIF, TFIIH; Pol II; and perhaps TFIIA. This minimal PIC, however, is often insufficient for initiation of transcription and generally does not form at all if the promoter is obscured within chromatin. Positive regulation, leading to transcription, is imposed by the activators and coactivators. Mediator interacts directly with TFIIH and TFIIE, allowing their recruitment to the PIC.

Choreography of Transcriptional Activation We can now begin to piece together the sequence of transcriptional activation events at a typical Pol II promoter (**Fig. 28-31**). The exact order of binding of some components may vary, but the model in Figure 28-31 illustrates the principles of activation as well as one common path. Many transcription activators have significant affinity for their binding sites even when the sites are within condensed chromatin. The binding of activators is often the event that triggers subsequent activation of the promoter. Binding of one activator may enable the binding of others, gradually displacing some nucleosomes.

Crucial remodeling of the chromatin then takes place in stages, facilitated by interactions between activators and HATs or enzyme complexes such as SWI/SNF, or both. In this way, a bound activator can draw in other components necessary for further chromatin remodeling to permit transcription of specific genes. The bound activators interact with the large Mediator complex. Mediator, in turn, provides an assembly surface for the binding of, first, TBP (or TFIID), then TFIIB, and then other components of the PIC, including Pol II. Mediator stabilizes the binding of Pol II and its associated transcription factors and greatly facilitates formation of the PIC. Complexity in these regulatory circuits is the rule rather than the exception, with multiple DNA-bound activators promoting transcription.

The script can change from one promoter to another. For example, many promoters have a different set of recognition sequences and may not have a TATA box, and in multicellular eukaryotes the subunit composition of factors such as TFIID can vary from one tissue to another. However, most promoters seem to require a precisely ordered assembly of components to initiate transcription. The assembly process is not always fast. For some genes it may take minutes; for certain genes of higher eukaryotes, the process can take days.

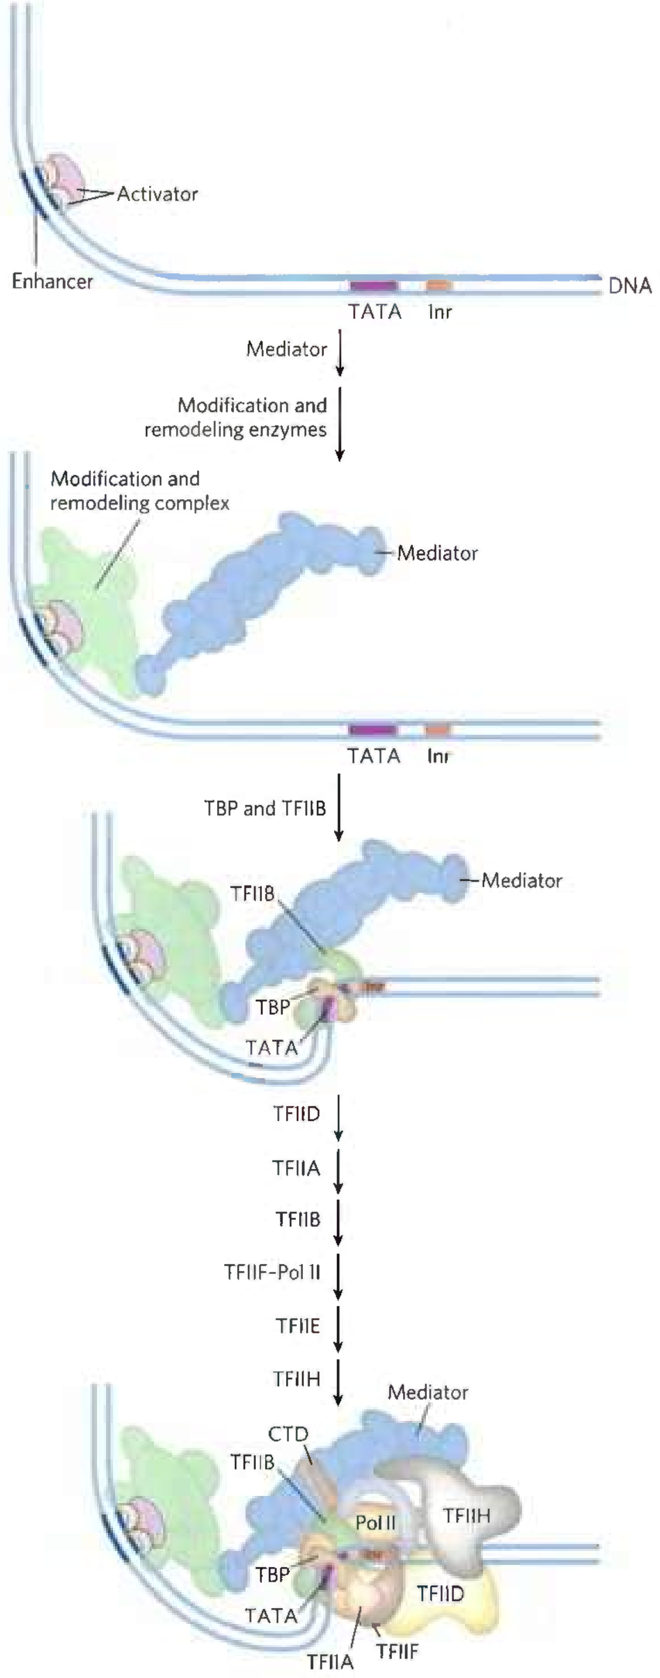

FIGURE 28-31 The components of transcriptional activation. Activators bind the DNA first. The activators recruit the histone modification/nucleosome remodeling complexes and a coactivator such as Mediator. Mediator facilitates the binding of TBP (or TFIID) and TFIIB, and the other basal transcription factors and Pol II then bind. Phosphorylation of the CTD of Pol II leads to transcription initiation (not shown). [Information from J. A. D'Alessio et al., *Mol. Cell* 36:924, 2009.]

The Genes of Galactose Metabolism in Yeast Are Subject to Both Positive and Negative Regulation

Some of the general principles described above can be illustrated by one well-studied eukaryotic regulatory circuit (**Fig. 28-32**). The enzymes required for the importation and metabolism of galactose in yeast are encoded by genes scattered over several chromosomes (**Table 28-3**). Each of the *GAL* genes is transcribed separately, and yeast cells have no operons like those in bacteria. However, all the *GAL* genes have similar promoters and are regulated coordinately by a common set of proteins. The promoters for the *GAL* genes consist of the TATA box and Inr sequences, as well as an upstream activator sequence (UAS_G) recognized by the transcription activator Gal4 protein (Gal4p). Regulation of gene expression by galactose entails an interplay between Gal4p and two other proteins, Gal80p and Gal3p. Gal80p forms a complex with Gal4p, preventing Gal4p from functioning as an activator of the *GAL* promoters. When galactose is present, it binds Gal3p, which then interacts with the Gal80p-Gal4p complex and allows Gal4p to function as an activator at the *GAL* promoters. As the various galactose genes are induced and their products build up, Gal3p may be replaced with Gal1p (a galactokinase needed for galactose metabolism that also acts as a regulator) for sustained activation of the regulatory circuit.

Other protein complexes also have a role in activating transcription of the *GAL* genes. These include the SAGA complex for histone acetylation and chromatin remodeling, the SWI/SNF complex for chromatin remodeling, and Mediator. The Gal4 protein is responsible for recruitment of these additional factors needed for transcriptional activation. SAGA may be the first and primary recruitment target for Gal4p.

Glucose is the preferred carbon source for yeast, as it is for bacteria. When glucose is present, most of the *GAL* genes are repressed—whether galactose is present or not. The *GAL* regulatory system described above is effectively overridden by a complex catabolite repression system that includes several proteins (not depicted in Fig. 28-32).

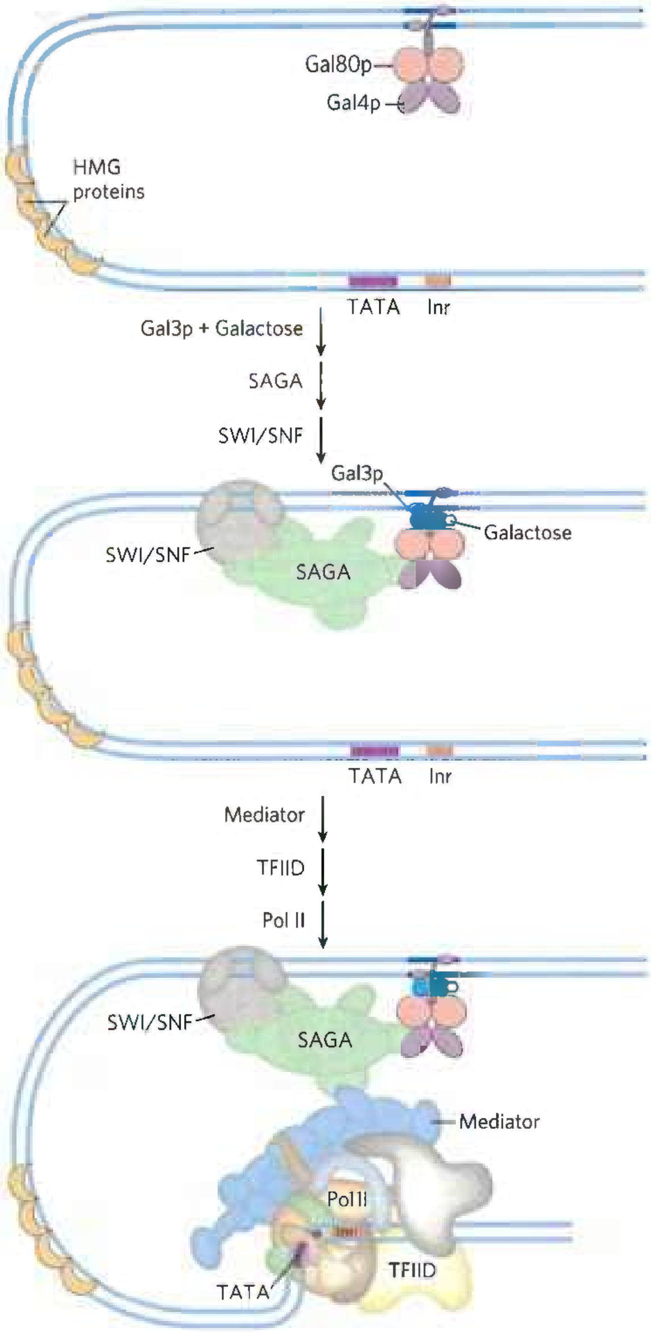

FIGURE 28-32 Regulation of transcription of *GAL* genes in yeast. Galactose imported into the yeast cell is converted to glucose 6-phosphate by a pathway involving five enzymes, whose genes are scattered over three chromosomes (see Table 28-3). Transcription of these genes is regulated by the combined actions of the proteins Gal4p, Gal80p, and Gal3p, with Gal4p playing the central role of transcription activator. The Gal4p-Gal80p complex is inactive. Binding of galactose to Gal3p leads to interaction of Gal3p with the Gal80p-Gal4p complex and activates Gal4p. The Gal4p subsequently recruits SAGA, Mediator, and TFIID to the galactose promoters, leading to recruitment of RNA polymerase II and initiation of transcription. Chromatin remodeling to allow transcription also requires a SWI/SNF complex.

Transcription Activators Have a Modular Structure

Transcription activators typically have a distinct structural domain for specific DNA binding and one or more additional domains for transcriptional activation or for interaction with other regulatory proteins. Interaction of two regulatory proteins is often mediated by domains containing leucine zippers (Fig. 28-15) or helix-loop-helix motifs (Fig. 28-16). We consider here three distinct types of structural domains used in activation by the transcription activators Gal4p, Sp1, and CTF1 (**Fig. 28-33a**).

Gal4p contains a zinc finger–like structure in its DNA-binding domain, near the amino terminus; this domain has six Cys residues that coordinate two Zn^{2+}. The protein functions as a homodimer (with dimerization mediated by interactions between two coiled coils) and binds to UAS_G, a palindromic DNA sequence about 17 bp long. Gal4p has a separate activation domain with many acidic amino acid residues. Experiments that substitute

TABLE 28-3 Genes of Galactose Metabolism in Yeast

Gene	Protein function	Chromosomal location	Protein size (number of residues)	Relative protein expression in different carbon sources		
				Glucose	Glycerol	Galactose

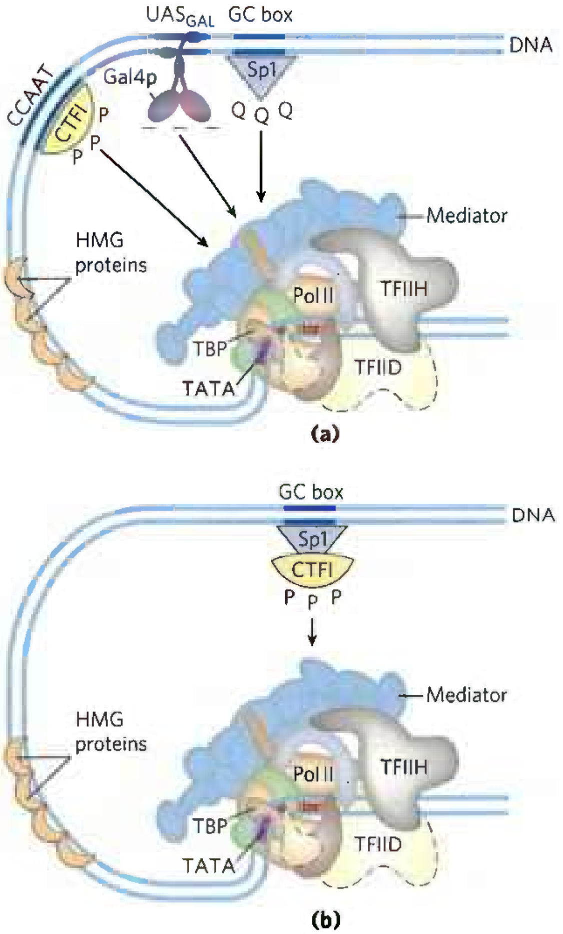

FIGURE 28-33 Transcription activators. (a) Typical activators such as CTF1, Gal4p, and Sp1 have a DNA-binding domain and an activation domain. The nature of the activation domain is indicated by symbols: − − −, acidic; Q Q Q, glutamine-rich; P P P, proline-rich. These proteins generally activate transcription by interacting with coactivator complexes such as Mediator. Note that the binding sites illustrated here are not generally found together near a single gene. (b) A chimeric protein containing the DNA-binding domain of Sp1 and the activation domain of CTF1 activates transcription if a GC box is present.

a variety of different peptide sequences for the **acidic activation domain** of Gal4p suggest that the acidic nature of this domain is critical to its function, although its precise amino acid sequence can vary considerably.

Sp1 (M_r 80,000) is a transcription activator for many genes in higher eukaryotes. Its DNA-binding site, the GC box (consensus sequence GGGCGG), is usually quite near the TATA box. The DNA-binding domain of the Sp1 protein is near its carboxyl terminus and contains three zinc fingers. Two other domains in Sp1 function in activation and are notable in that 25% of their amino acid residues are Gln. A wide variety of other activator proteins also have these **glutamine-rich domains**.

CTF1 (*C*CAAT-binding *t*ranscription *f*actor 1) belongs to a family of transcription activators that bind a sequence called the CCAAT site (its consensus sequence is TGGN$_6$GCCAA, where N is any nucleotide). The DNA-binding domain of CTF1 contains many basic amino acid residues, and the binding region is probably arranged as an α helix. This protein has neither a helix-turn-helix motif nor a zinc finger motif; its DNA-binding mechanism is not yet clear. CTF1 has a **proline-rich activation domain**, with Pro accounting for more than 20% of the amino acid residues.

The discrete activation and DNA-binding domains of regulatory proteins often act completely independently, as has been demonstrated in "domain-swapping" experiments. Genetic engineering techniques (Chapter 9) can join the proline-rich activation domain of CTF1 to the DNA-binding domain of Sp1 to create a protein that, like intact Sp1, binds to GC boxes on the DNA and activates transcription at a nearby promoter (as in Fig. 28-33b). The DNA-binding domain of Gal4p has similarly been replaced experimentally with the DNA-binding domain of the *E. coli* LexA repressor (of the SOS response; Fig. 28-21). This chimeric protein neither binds at UAS$_G$

nor activates the yeast *GAL* genes (as would intact Gal4p) unless the UAS_G sequence in the DNA is replaced by the LexA recognition site.

Eukaryotic Gene Expression Can Be Regulated by Intercellular and Intracellular Signals

The effects of steroid hormones (and of thyroid and retinoid hormones, which have a similar mode of action) provide additional well-studied examples of the modulation of eukaryotic regulatory proteins by direct interaction with molecular signals (see Fig. 12-34). Unlike other types of hormones, steroid hormones do not have to bind to plasma membrane receptors. Instead, they can interact with intracellular receptors that are transcription activators. Steroid hormones too hydrophobic to dissolve readily in the blood (estrogen, progesterone, and cortisol, for example) travel on specific carrier proteins from their point of release to their target tissues. In the target tissue, the hormone passes through the plasma membrane by simple diffusion. Once inside the cell, the hormone interacts with one of two types of steroid-binding nuclear receptor (**Fig. 28-34**). In both cases, the hormone-receptor complex acts by binding to highly specific DNA sequences called **hormone response elements (HREs)**, thereby altering gene expression. Acting at these sites, the receptors act as transcription activators, recruiting coactivators and Pol II (plus its associated transcription factors) to trigger transcription of the gene.

The DNA sequences (HREs) to which hormone-receptor complexes bind are similar in length and arrangement for the various steroid hormones, but they differ in sequence. Each receptor has a consensus HRE sequence (**Table 28-4**) to which the hormone-receptor complex binds well, with each consensus consisting of two six-nucleotide sequences, either contiguous or separated by three nucleotides, in tandem or in a palindromic arrangement. The hormone receptors have a highly conserved DNA-binding domain with two zinc fingers (**Fig. 28-35**). The hormone-receptor complex binds to the DNA as a dimer, with the zinc finger domains of each monomer recognizing one of the six-nucleotide sequences. The ability of a given hormone to act through the hormone-receptor complex to alter the expression of a specific

FIGURE 28-34 Mechanisms of steroid hormone receptor function. There are two types of steroid-binding nuclear receptors. (a) Monomeric type I receptors (NR) are found in the cytoplasm, in a complex with the heat shock protein Hsp70. Receptors for estrogen, progesterone, androgens, and glucocorticoids are of this type. When the steroid hormone binds, the Hsp70 dissociates and the receptor dimerizes, exposing a nuclear localization signal. The dimeric receptor, with hormone bound, migrates to the nucleus, where it binds to a hormone response element (HRE) and acts as a transcription activator. The activity of the receptor can be repressed by binding to an lncRNA (such as GAS5), which competes directly with binding to the HRE. (b) Type II receptors, by contrast, are always in the nucleus, bound to an HRE in the DNA and to a corepressor that renders the receptor inactive. The thyroid hormone receptor (TR) is of this type. The hormone migrates through the cytoplasm and diffuses across the nuclear membrane. In the nucleus it binds to a heterodimer consisting of the thyroid hormone receptor and the retinoid X receptor (RXR). A conformation change leads to dissociation of the corepressor, and the receptor then functions as a transcription activator.

FIGURE 28-35 Typical steroid hormone receptors. These receptor proteins have a binding site for the hormone, a DNA-binding domain, and a region that activates transcription of the regulated gene. The highly conserved DNA-binding domain has two zinc fingers. The sequence shown here is that for the estrogen receptor, but the residues in bold type are common to all steroid hormone receptors.

gene depends on the exact sequence of the HRE, its position relative to the gene, and the number of HREs associated with the gene.

The ligand-binding region of the receptor protein—always at the carboxyl terminus—is specific to the particular receptor. For example, in the ligand-binding region, the glucocorticoid receptor is only 30% similar to the estrogen receptor and 17% similar to the thyroid hormone receptor. The size of the ligand-binding region varies dramatically; in the vitamin D receptor it has only 25 amino acid residues, whereas in the mineralocorticoid receptor it has 603 residues. Mutations that change one amino acid residue in these regions can result in loss of responsiveness to a specific hormone. Some humans unable to respond to cortisol, testosterone, vitamin D, or thyroxine have mutations of this type.

P2 The lncRNAs introduce another dimension to regulation by hormone receptors. An lncRNA called GAS5 (*g*rowth *a*rrest *s*pecific 5) inhibits transcriptional activation by the glucocorticoid receptor by directly competing with DNA for receptor binding. GAS5 also inhibits activity of the closely related androgen, progesterone, and mineralocorticoid receptors. In addition, GAS5 interacts with and sequesters an miRNA called miR-21, which interacts with and inhibits the activity of some regulatory proteins that act as tumor suppressors. Expression of GAS5 is suppressed in a wide range of tumors, resulting in increased expression of steroid hormones, higher levels of active miR-21, and faster tumor growth. Low GAS5 levels thus correlate with worsened outcomes for cancer patients, making this lncRNA a subject of intense ongoing investigation.

Some hormone receptors, including the human progesterone receptor, activate transcription with the aid of a different lncRNA of ~700 nucleotides that acts as a coactivator—**steroid receptor RNA activator (SRA)**. SRA is part of a ribonucleoprotein complex, but it is the RNA component that is required for transcription coactivation. The detailed set of interactions between SRA and other components of the regulatory systems for these genes remains to be worked out.

Regulation Can Result from Phosphorylation of Nuclear Transcription Factors

We noted in Chapter 12 that the effects of insulin on gene expression are mediated by a series of steps leading ultimately to the activation of a protein kinase in the nucleus that phosphorylates specific DNA-binding proteins, thereby altering their ability to act as transcription factors (see Fig. 12-22). This general mechanism mediates the effects of many nonsteroid hormones. For example, the β-adrenergic pathway that leads to elevated levels of cytosolic cAMP, which acts as a second messenger in both eukaryotes and bacteria (Fig. 28-18), also affects the transcription of a set of genes, each of which is located near a specific DNA sequence called a **cAMP response element (CRE)**. The catalytic subunit of protein kinase A, released when cAMP levels rise (see Fig. 12-6), enters the nucleus and phosphorylates a nuclear protein, the **CRE-binding protein (CREB)**. When phosphorylated, CREB binds to CREs near certain genes and acts as a transcription factor, turning on expression of these genes.

Many Eukaryotic mRNAs Are Subject to Translational Repression

P1 Regulation at the level of translation assumes a much more prominent role in eukaryotes than in bacteria and is observed in a range of cellular situations. In contrast to the tight coupling of transcription and translation in bacteria, the transcripts generated in a eukaryotic nucleus must be processed and transported to the cytoplasm before translation. This can impose a significant delay on the appearance of a protein. When a rapid increase in protein production is needed, a translationally repressed mRNA already in the cytoplasm can be activated for translation without delay. Translational regulation may play an especially important role in regulating certain very long eukaryotic genes (a few are measured in the millions of base pairs), for which transcription and mRNA processing can require many hours. Some genes are regulated at both the transcriptional and translational stages, with the latter playing a role in the fine-tuning of cellular protein levels. In some non-nucleated cells, such as reticulocytes (immature erythrocytes), transcriptional control is entirely unavailable and translational control of stored mRNAs becomes essential. As described below, translational controls can also have spatial significance during development, when the regulated translation of prepositioned mRNAs creates a local gradient of the protein product.

Eukaryotes have at least four main mechanisms of translational regulation:

1. Translation initiation factors are subject to phosphorylation by protein kinases. The phosphorylated forms are often less active and cause a general depression of translation in the cell.
2. Some proteins bind directly to mRNA and act as translational repressors, many of them binding at specific sites in the 3′ untranslated region (3′UTR). So positioned, these proteins interact with other translation initiation factors bound to the mRNA, or with the 40S ribosomal subunit, to prevent translation initiation (**Fig. 28-36**).
3. Binding proteins, present in eukaryotes from yeast to mammals, disrupt the interaction between eIF4E and eIF4G (see Fig. 27-27). The mammalian versions are known as 4E-BPs (eIF4E binding proteins). When cell growth is slow, these proteins limit translation by binding to the site on eIF4E that normally interacts with eIF4G. When cell growth resumes or increases in response to growth factors or other stimuli, the binding proteins are inactivated by protein kinase–dependent phosphorylation.
4. RNA-mediated regulation of gene expression often occurs at the level of translational repression, often by the binding of ncRNAs to mRNAs.

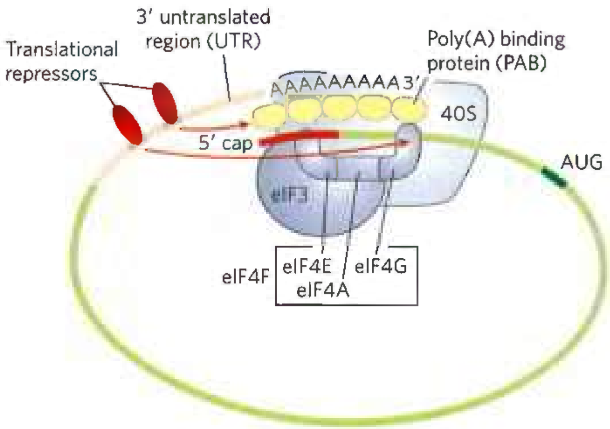

FIGURE 28-36 Translational regulation of eukaryotic mRNA. One of the most important mechanisms for translational regulation in eukaryotes is the binding of translational repressors (RNA-binding proteins) to specific sites in the 3′ untranslated region (3′UTR) of the mRNA. These proteins interact with eukaryotic initiation factors or with the ribosome to prevent or slow translation.

The variety of translational regulation mechanisms provides flexibility, allowing focused repression of a few mRNAs or global regulation of all cellular translation.

Translational regulation has been particularly well studied in reticulocytes. One such mechanism in these cells involves eIF2, the initiation factor that binds to the initiator tRNA and conveys it to the ribosome; when Met-tRNA has bound to the P site, the factor eIF2B binds to eIF2, recycling it with the aid of GTP binding and hydrolysis. The maturation of reticulocytes includes destruction of the cell nucleus, leaving behind a plasma membrane packed with hemoglobin. Messenger RNAs deposited in the cytoplasm before the loss of the nucleus allow for the replacement of hemoglobin. When reticulocytes become deficient in iron or heme, the translation of globin mRNAs is repressed. A protein kinase called **HCR (hemin-controlled repressor)** is then activated, catalyzing the phosphorylation of eIF2. When phosphorylated, eIF2 forms a stable complex with eIF2B that sequesters the eIF2, making it unavailable for participation in translation. In this way, the reticulocyte coordinates the synthesis of globin with the availability of heme.

Posttranscriptional Gene Silencing Is Mediated by RNA Interference

In higher eukaryotes, including nematodes, fruit flies, plants, and mammals, microRNAs (miRNAs) mediate the silencing of many genes. In a phenomenon first described and explained by Craig Mello and Andrew Fire, the RNAs function by interacting with mRNAs, often in the 3′UTR, resulting in either degradation of the mRNA or inhibition of translation. In either case, the mRNA, and thus the gene that produces it, is silenced. This form of gene regulation controls developmental timing in at least some organisms. It is also used as a mechanism to protect against invading RNA viruses (particularly important in plants, which lack an immune system) and to control the activity of transposons. In addition, small RNA molecules may play a critical (as yet undefined) role in the formation of heterochromatin.

Many miRNAs are present only transiently during development, and these are sometimes referred to as **small temporal RNAs (stRNAs)**. Thousands of different miRNAs have been identified in higher eukaryotes, and they may affect the regulation of a third of mammalian genes. They are transcribed as precursor RNAs ~70 nucleotides long, with internally complementary sequences that form hairpinlike structures. Details of the pathway for processing of miRNAs were described in Fig. 26-26). The precursors are cleaved by endonucleases such as Drosha and Dicer to form short duplexes of 20 to 25 nucleotides. One strand of the processed miRNA is transferred to the target mRNA (or to a viral or transposon RNA), leading to inhibition of translation or degradation of the mRNA (**Fig. 28-37a**). Some miRNAs bind to and affect a single mRNA and thus affect expression of only one gene. Others interact with multiple mRNAs and form the mechanistic core of regulons that coordinate the expression of multiple genes.

This gene regulation mechanism has an interesting and very useful practical side. If an investigator introduces into an organism a duplex RNA molecule corresponding in sequence to virtually any mRNA, Dicer cleaves the duplex into short segments, called **small interfering RNAs (siRNAs)**. These bind to the mRNA and silence it (Fig. 28-37b). The process is known as **RNA interference (RNAi)**. In plants, almost any gene can be effectively shut down in this way. Nematodes can readily ingest entire functional RNAs, and simply introducing the duplex RNA into the worm's diet produces very effective suppression of the target gene. The technique is an important tool in the ongoing efforts to study gene function, because it can disrupt gene function without creating a mutant organism. The procedure can be applied to humans as well. Laboratory-produced siRNAs have been used to block HIV and poliovirus infections in cultured human cells for a week or so at a time. The wider application of RNAi-based pharmaceuticals was initially stymied by the difficulty inherent in delivering RNAi molecules to their required target, given the many nucleases that degrade RNA in human tissues. With recent advances in delivery methods, there are now more than a dozen RNAi pharmaceuticals in advanced clinical trials to treat a range of conditions, from familial amyloidotic polyneuropathy to viral infections and cancer.

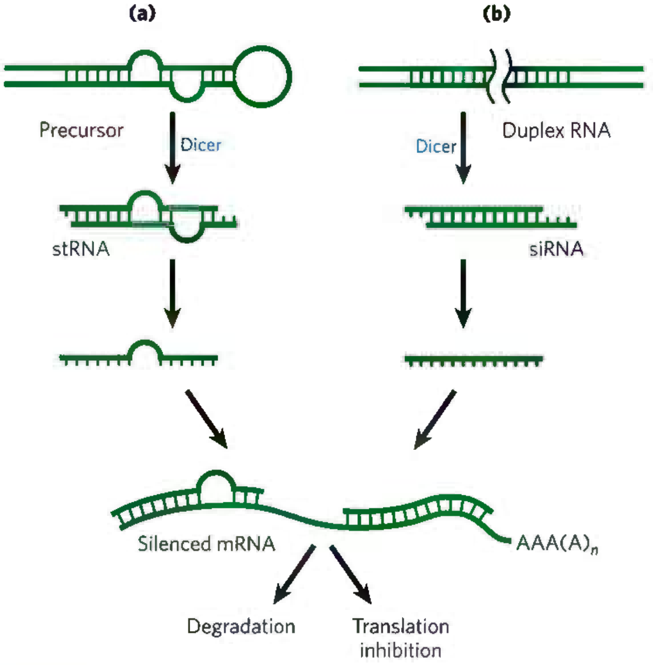

FIGURE 28-37 Gene silencing by RNA interference. (a) Small temporal RNAs (stRNAs, a class of miRNAs) are generated by Dicer-mediated cleavage of longer precursors that fold to create duplex regions. The stRNAs then bind to mRNAs, leading to degradation of mRNA or inhibition of translation. (b) Double-stranded RNAs designed to interact with a particular target and to function as Dicer substrates can be constructed and introduced into a cell. Dicer processes the duplex RNAs into small interfering RNAs (siRNAs), which interact with the target mRNA. Again, either the mRNA is degraded or translation is inhibited.

RNA-Mediated Regulation of Gene Expression Takes Many Forms in Eukaryotes

All RNAs (regardless of their length) that do not encode proteins, including rRNAs and tRNAs, come under the general designation of ncRNAs. Mammalian genomes encode more ncRNAs than coding mRNAs. The ncRNAs in eukaryotes include miRNAs, described above; snRNAs, involved in RNA splicing (see Fig. 26-16); snoRNAs, involved in rRNA modification (see Fig. 26-24); and lncRNAs, already encountered in this chapter. Not surprisingly, additional functional classes of ncRNAs are still being discovered. P2 Here we describe a few more examples of ncRNAs that participate in gene regulation, which are designated lncRNAs when their length exceeds 200 nucleotides.

Heat shock factor 1 (HSF1) is an activator protein that, in nonstressed cells, exists as a monomer bound by the chaperone Hsp90. Under stress conditions, HSF1 is released from Hsp90 and trimerizes. The HSF1 trimer binds to DNA and activates transcription of genes encoding products required to deal with the stress. An lncRNA called HSR1 (heat shock RNA 1; ~600 nucleotides) stimulates HSF1 trimerization and DNA binding. HSR1 does not act alone; it functions in a complex with the translation elongation factor eEF1A.

Additional RNAs affect transcription in a variety of ways. A 331 nucleotide lncRNA called 7SK, abundant in mammals, binds to the Pol II transcription elongation factor pTEFb (see Table 26-2) and represses transcript elongation. The ncRNA B2 (~178 nucleotides) binds directly to Pol II during heat shock and represses transcription. The B2-bound Pol II assembles into stable PICs, but transcription is blocked. The mechanism that allows HSF1-responsive genes to be expressed in the presence of B2 remains to be worked out.

The recognized roles of ncRNAs in gene expression and in many other cellular processes are rapidly expanding. At the same time, the study of the biochemistry of gene regulation is becoming much less protein-centric.

Development Is Controlled by Cascades of Regulatory Proteins

For sheer complexity and intricacy of coordination, the patterns of gene regulation that bring about development of a zygote into a multicellular animal or plant have no peer. Development requires transitions in morphology and protein composition that depend on tightly coordinated changes in expression of the genome. More genes are expressed during early development than in any other part of the life cycle. For example, in the sea urchin, an oocyte has about 18,500 *different* mRNAs, compared with about 6,000 different mRNAs in the cells of a typical differentiated tissue. The mRNAs in the oocyte give rise to a cascade of events that regulate the expression of many genes across both space and time.

Several organisms have emerged as important model systems for the study of development, because they are easy to maintain in a laboratory and have relatively short generation times. These include nematodes, fruit flies, zebra fish, mice, and the plant *Arabidopsis*. Here, we provide a brief discussion of the development of fruit flies. Our understanding of the molecular events during development of *Drosophila melanogaster* is particularly well advanced and can be used to illustrate patterns and principles of general significance.

The life cycle of the fruit fly includes complete metamorphosis during its progression from an embryo to an adult (**Fig. 28-38**). Among the most important characteristics of the embryo are its **polarity** (the anterior and posterior parts of the animal are readily distinguished, as are its dorsal and ventral surfaces) and its **metamerism** (the embryo body is made up of serially repeating segments, each with characteristic features). During development, these segments become organized into a head, thorax, and abdomen. Each segment of the adult thorax has a different set of appendages. Development of this complex pattern is under genetic control, and a variety of pattern-regulating genes have been discovered that greatly affect the organization of the body.

The *Drosophila* egg, along with 15 nurse cells, is surrounded by a layer of follicle cells (**Fig. 28-39**). As the egg cell forms (before fertilization), mRNAs and proteins originating in the nurse and follicle cells are deposited in the egg cell, where some play a critical role in development. Once a fertilized egg is laid, its nucleus divides and the nuclear descendants continue to divide in synchrony every 6 to 10 min. Plasma membranes are not formed around the nuclei, which are distributed within the egg cytoplasm, forming a syncytium. Between the eighth and eleventh rounds of nuclear division, the nuclei migrate to the outer layer of the egg, forming a monolayer of nuclei surrounding the common yolk-rich cytoplasm; this is the syncytial blastoderm. After a few additional divisions, membrane invaginations surround the nuclei to create a layer of cells that form the cellular blastoderm. At this stage, the mitotic cycles in the various cells lose their synchrony. The developmental fate of the cells is determined by the mRNAs and proteins originally deposited in the egg by the nurse and follicle cells.

Proteins that, through changes in local concentration or activity, cause the surrounding tissue to take up a particular shape or structure are sometimes referred to as **morphogens**; they are the products of pattern-regulating genes. As defined by Christiane Nüsslein-Volhard, Edward B. Lewis, and Eric F. Wieschaus, three major classes of pattern-regulating genes—maternal, segmentation, and homeotic genes—function in successive stages of development to specify the basic features of the *Drosophila* embryo body. **Maternal genes** are expressed in the unfertilized egg, and the resulting **maternal mRNAs** remain dormant until fertilization.

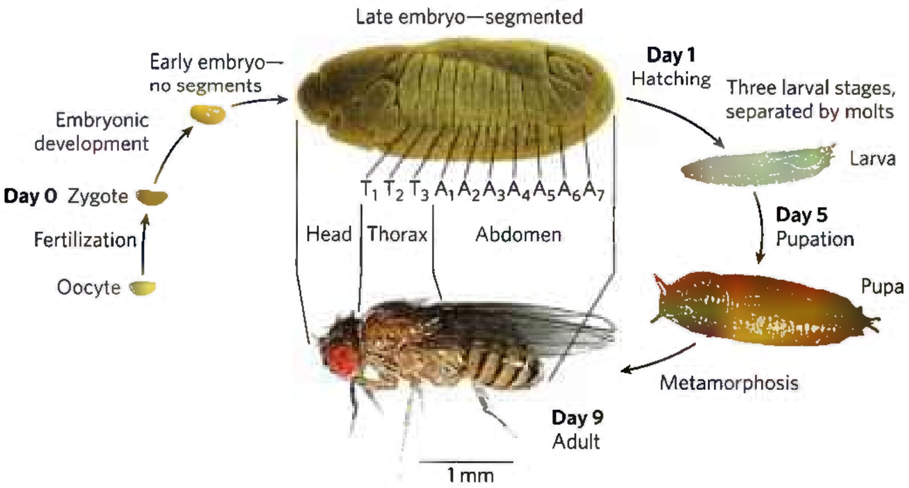

FIGURE 28-38 Life cycle of the fruit fly *Drosophila melanogaster*. *Drosophila* undergoes a complete metamorphosis, which means that the adult insect is radically different in form from its immature stages, a transformation that requires extensive alterations during development. By the late embryonic stage, segments have formed, each containing specialized structures from which the various appendages and other features of the adult fly will develop. [Late embryo: Courtesy of F. R. Turner, Department of Biology, University of Indiana, Bloomington. Other photos: Courtesy of Prof. Dr. Christian Klambt, Westfälische Wilhelms-Universität Münster, Institut für Neuro- und Verhaltensbiologie.]

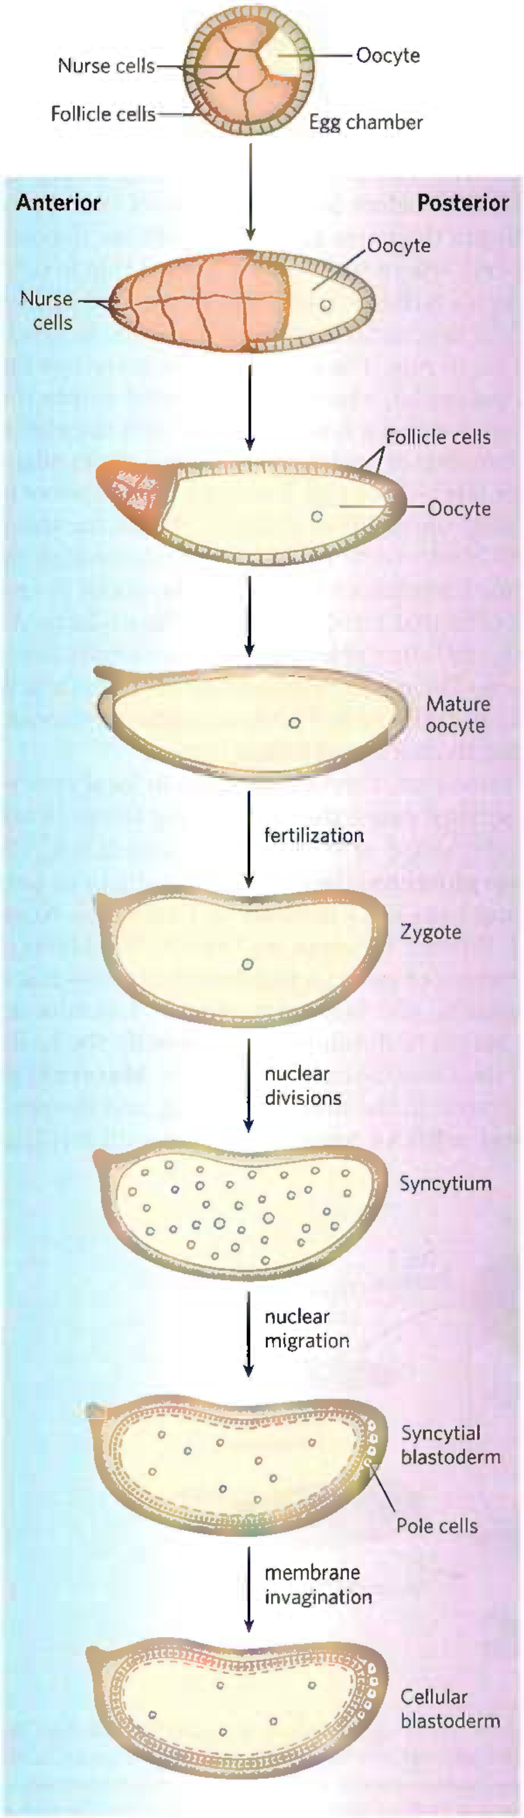

FIGURE 28-39 Early development in *Drosophila*. During development of the egg, maternal mRNAs and proteins are deposited in the developing oocyte (unfertilized egg cell) by nurse cells and follicle cells. After fertilization, the nuclei of the egg divide in synchrony within the common cytoplasm (syncytium), then migrate to the periphery. Membrane invaginations surround the nuclei to create a monolayer of cells at the periphery; this is the cellular blastoderm stage. During the early nuclear divisions, several nuclei at the far posterior become pole cells, which later become the germ-line cells.

These provide most of the proteins needed in very early development, until the cellular blastoderm is formed. Some of the proteins encoded by maternal mRNAs direct the spatial organization of the developing embryo at early stages, establishing its polarity. **Segmentation genes**, transcribed after fertilization, direct the formation of the proper number of body segments. At least three subclasses of segmentation genes act at successive stages: **gap genes** divide the developing embryo into several broad regions; **pair-rule genes**, together with **segment polarity genes**, define 14 stripes that become the 14 segments of a normal embryo. **Homeotic genes** are expressed still later; they specify which organs and appendages will develop in particular body segments.

If all cells divided to produce two identical daughter cells, multicellular organisms would never be more than a ball of identical cells. A key event in very early development is establishment of mRNA and protein gradients along the body axes, producing asymmetric cell divisions and different cell fates. Some maternal mRNAs have protein products that diffuse through the cytoplasm to create an asymmetric distribution in the egg. Different cells in the cellular blastoderm therefore inherit different amounts of these proteins, setting the cells on different developmental paths. An example is the *bicoid* gene. The *bicoid* gene product is a major anterior morphogen. The mRNA from the *bicoid* gene is synthesized by nurse cells and deposited in the unfertilized egg near its anterior pole. Translated soon after fertilization, the Bicoid protein diffuses through the cell to create, by the seventh nuclear division, a concentration gradient radiating out from the anterior pole (**Fig. 28-40**). The Bicoid protein contains a homeodomain (p. 1062), encoded by a gene sequence motif called a homeobox and found in many proteins involved in regulating development. Bicoid is multifunctional—a transcription factor that activates the expression of several segmentation genes and also a translational repressor that inactivates certain mRNAs. The amount of Bicoid protein in various parts of the embryo increases or decreases the expression of other genes in a threshold-dependent manner. As its concentration varies along its gradient, interactions of the *bicoid* gene product with proteins and RNAs encoded by the *nanos, pumilio, caudal, hunchback*, and other regulatory genes also vary to produce different effects along the axis of the developing organism. This results in different developmental fates of cells in the blastoderm, depending on their location.

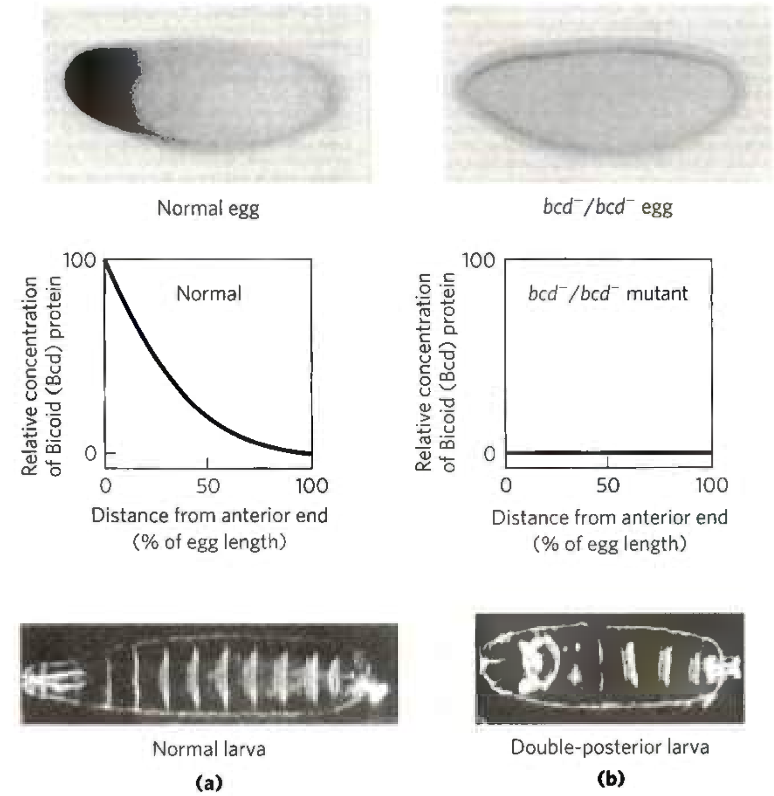

FIGURE 28-40 Distribution of a maternal gene product in a *Drosophila* egg. (a) Micrograph of an immunologically stained egg (top), showing distribution of the *bicoid* (*bcd*) gene product. The graph shows stain intensity along the length of the egg. This distribution is essential for normal development of the anterior structures in the larva (bottom). (b) If the *bcd* gene is not expressed by the mother (bcd^-/bcd^- mutant) and thus no *bicoid* mRNA is deposited in the egg, the resulting larva has two posteriors (and soon dies). [Republished with permission of Elsevier, from "The bicoid protein determines position in the *Drosophila* embryo in a concentration-dependent manner" by Wolfgang Driever and Christiane Nüsslein-Volhard, *Cell* 54:83–93, July 1, 1988; permission conveyed through Copyright Clearance Center, Inc.]

Humans do not resemble fruit flies, but the genes and mechanisms involved in development are nevertheless highly conserved. This can be seen in the gene clusters encoding the homeotic or ***Hox* genes**, the latter term derived from homeobox. *Drosophila* has one such cluster, while humans have four (**Fig. 28-41**), with the genes within the clusters remarkably similar from nematodes to humans.

The many regulatory genes in these three classes direct the development of an adult fly, with a head, thorax, and abdomen, with the proper number of segments, and with the correct appendages on each segment. Although embryogenesis takes about a day to complete, all these genes are activated during the first four hours. Some mRNAs and proteins are present for only a few minutes at specific points during this period. Some of the genes code for transcription factors that affect the expression of other genes in a kind of developmental cascade. Regulation at the level of translation also occurs, and many of the regulatory genes encode translational repressors, most of which bind to the 3′UTR of the mRNA (Fig. 28-36). P1 Because many mRNAs are deposited in the egg long before their translation is required, translational repression provides an especially important avenue for regulation in developmental pathways.

Many of the principles of development outlined above apply to other eukaryotes, from nematodes to humans. Some of the regulatory proteins are conserved. For example, the products of the homeobox-containing genes *HOXA7* in mouse and *antennapedia* in fruit fly differ in only one amino acid residue. Of course, although the molecular regulatory mechanisms may be similar, many of the ultimate developmental events are not conserved (humans do not have wings or antennae). The different outcomes are brought about by differences in the downstream target genes controlled by the *Hox* genes. The discovery of structural determinants with identifiable molecular functions is the first step in understanding the molecular events underlying development. As more genes and their protein products are discovered, the biochemical side of this vast puzzle will be elucidated in increasingly rich detail.

Stem Cells Have Developmental Potential That Can Be Controlled

If we can understand development, and the mechanisms of gene regulation behind it, we can control it. An adult human has many different types of tissues. Many of the cells are terminally differentiated and no longer divide. If an organ malfunctions due to disease, or a limb is lost

FIGURE 28-41 The *Hox* gene clusters and their effects on development. (a) Each *Hox* gene in the fruit fly is responsible for the development of structures in a defined part of the body and is expressed in defined regions of the embryo, as labeled. (b) *Drosophila* has one *Hox* gene cluster; the human genome has four. Many of these genes are highly conserved in multicellular animals. Evolutionary relationships, as indicated by sequence alignments, between genes in the fruit fly *Hox* gene cluster and those in the mammalian *Hox* gene clusters are shown by dashed lines. Similar relationships among the four sets of mammalian *Hox* genes are indicated by vertical alignment. [(a) Information from F. R. Turner, University of Indiana, Department of Biology.]

in an accident, the tissues are not readily replaced. Most cells, because of the regulatory processes in place, or even because of the loss of some or all of the genomic DNA, are not easily reprogrammed. Medical science has made organ transplants possible, but organ donors are a limited resource and organ rejection remains a major medical problem. If humans could regenerate their own organs or limbs or nervous tissue, rejection would no longer be an issue. Cures for kidney failure or neurodegenerative disorders could become reality.

The key to tissue regeneration lies in **stem cells**—cells that have retained the capacity to differentiate into various tissues. In humans, after an egg is fertilized, the first few cell divisions create a ball of **totipotent** cells, called the morula, that have the capacity to differentiate individually into any tissue or even into a complete organism (**Fig. 28-42**). Continued cell division produces a hollow ball, the blastocyst. The outer cells of the blastocyst eventually form the placenta. The inner layers form the germ layers of the developing fetus—the ectoderm, mesoderm, and endoderm. These

FIGURE 28-42 Totipotent and pluripotent stem cells. Cells at the morula stage are totipotent and have the capacity to differentiate into a complete organism. The source of pluripotent embryonic stem cells is the cells in the cavity of the blastocyst. Pluripotent cells give rise to many tissue types but cannot form complete organisms.

cells are **pluripotent**: they can give rise to cells of all three germ layers and can differentiate into many types of tissues. However, they cannot differentiate into a complete organism. Some of these cells are **unipotent**: they can develop into only one type of cell and/or tissue. It is the pluripotent cells of the blastocyst, the **embryonic stem cells**, that are currently used in embryonic stem cell research.

Stem cells have two functions: to replenish themselves and, at the same time, provide cells that can differentiate. These tasks are accomplished in multiple ways (**Fig. 28-43a**). All or parts of the stem cell population can, in principle, be involved in replenishment, differentiation, or both.

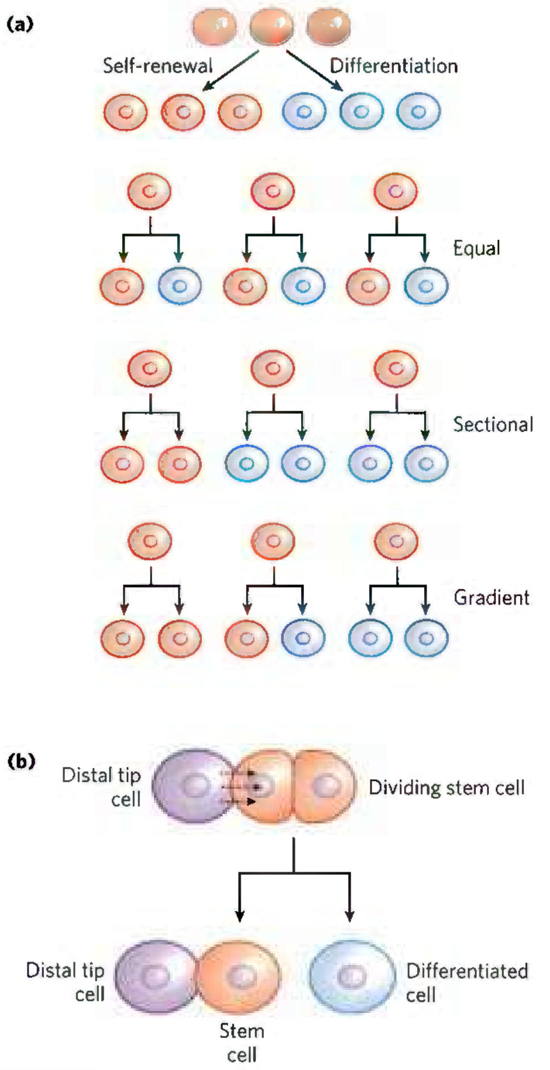

FIGURE 28-43 Stem cell proliferation versus differentiation and development. Stem cells must strike a balance between self-renewal and differentiation. (a) Some possible cell division patterns that allow the replenishment of stem cells and production of some differentiated cells. Each cell may produce one stem cell and one differentiated cell, or two differentiated cells, or two stem cells in defined parts of the tissue or culture. Or a gradient of growth conditions can be established, with cell fates differing from one end of the gradient to the other. (b) Establishing a developmental niche through stem cell contact with a cell or group of cells. Molecular signals provided by the niche cells (in this case, in plants, a distal tip cell) help orient the mitotic spindle for stem cell division and ensure that one daughter cell retains stem cell properties.

Other types of stem cells can potentially be used for medical benefit. In the adult organism, **adult stem cells**, as products of additional differentiation, have a more limited potential for further development than do embryonic stem cells. For example, the hematopoietic stem cells of bone marrow can give rise to many types of blood cells and also to cells with the capacity to regenerate bone. They are referred to as **multipotent**. However, these cells cannot differentiate into a liver or kidney or neuron. Adult stem cells are often said to have a **niche**, a microenvironment that promotes stem cell maintenance while allowing differentiation of some daughter cells as replacements for cells in the tissue they serve (Fig. 28-43b). Hematopoietic stem cells in the bone marrow occupy a niche in which signaling from neighboring cells and other cues maintain the stem cell lineage. At the same time, some daughter cells differentiate to provide needed blood cells. Understanding the niche in which stem cells operate, and the signals the niche provides, is essential in efforts to harness the potential of stem cells for tissue regeneration. The identification and culturing of pluripotent stem cells from human blastocysts was reported by James Thomson and colleagues in 1998. This advance led to the long-term availability of established cell lines for research.

All stem cells present problems for human medical applications. Adult stem cells have a limited capacity to regenerate tissues, are generally present in small numbers, and are hard to isolate from an adult human. Embryonic stem cells have much greater differentiation potential and can be cultured to generate large numbers of cells, but their use is accompanied by ethical concerns related to the necessary destruction of human embryos. Identifying a source of plentiful and medically useful stem cells that does not raise such concerns remains a major goal of medical research.

Our ability to culture stem cells (i.e., maintain them in an undifferentiated state), and to manipulate them to grow and differentiate into particular tissues, is very much a function of our understanding of developmental biology.

Thus far, mouse and human embryonic stem cells have been used for most research. Although both types of stem cells are pluripotent, they require very different culture conditions, optimized to allow cell division indefinitely without differentiation. Mouse embryonic stem cells are grown on a layer of gelatin and require the presence of leukemia inhibitory factor (LIF). Human embryonic stem cells are grown on a feeder layer of mouse embryonic fibroblasts and require basic fibroblast growth factor (bFGF, or FGF2). The use of a feeder cell layer implies that the mouse cells are providing a diffusible product or some surface signal, not yet known, that is needed by human stem cells to either promote cell division or prevent differentiation.

A significant advance, reported in 2007, centers on success in reversing differentiation. In effect, skin

South America has several species of seed-eating finches, commonly called grassquits. About 3 million years ago, a small group of grassquits, of a single species, took flight from the continent's Pacific coast. Perhaps driven by a storm, they lost sight of land and traveled nearly 1,000 km. Small birds such as these might easily have perished on such a journey, but the smallest of chances brought this group to a newly formed volcanic island in an archipelago later to be known as the Galápagos. It was a virgin landscape with untapped plant and insect food sources, and the newly arrived finches survived. Over the years, new islands formed and were colonized by new plants and insects — and by the finches. The birds exploited the new resources on the islands, and groups of birds gradually specialized and diverged into new species. By the time Charles Darwin stepped onto the islands in 1835, many different finch species were to be found on the various islands of the archipelago, feeding on seeds, fruits, insects, pollen, or even blood.

The diversity of living creatures was a source of wonder for humans long before scientists sought to understand its origins. The extraordinary insight handed down to us by Darwin, inspired in part by his encounter with the Galápagos finches, provided a broad explanation for the existence of organisms with a vast array of appearances and characteristics. It also gave rise to many questions about the mechanisms underlying evolution. Answers to those questions have started to appear, first through the study of genomes and nucleic acid metabolism in the last half of the twentieth century, and more recently through an emerging field nicknamed evo-devo — a blend of evolutionary and developmental biology.

In its modern synthesis, the theory of evolution has two main elements: mutations in a population generate genetic diversity; natural selection then acts on this diversity to favor individuals with more useful genomic tools and to disfavor others. Mutations occur at significant rates in every individual's genome, in every cell (see Section 8.3). Advantageous mutations in single-celled organisms or in the germ line of multicellular organisms can be inherited, and they are more likely to be inherited (that is, passed on to greater numbers of offspring) if they confer an advantage. It is a straightforward scheme. But many have wondered whether it is enough to explain, say, the many different beak shapes in the Galápagos finches or the diversity of size and shape among mammals. Until recent decades, there were several widely held assumptions about the evolutionary process: that many mutations and new genes would be needed to bring about a new physical structure, that more-complex organisms would have larger genomes, and that very different species would have few genes in common. All of these assumptions were wrong.

Modern genomics has revealed that the human genome contains fewer genes than expected — not many more than the fruit fly genome and fewer than some amphibian genomes. The genomes of every mammal, from mouse to human, are surprisingly similar in the number, types, and chromosomal arrangement of genes. Meanwhile, evo-devo is telling us how complex and very different creatures can evolve within these genomic realities.

In the late nineteenth century, English biologist William Bateson studied animals with homeotic mutations — creatures with body parts growing in the wrong location. Bateson used his observations to challenge the Darwinian notion that evolutionary change would have to be gradual. Recent studies of the genes that control organismal development have put an exclamation point on Bateson's ideas. Subtle changes in regulatory patterns during development, reflecting just one or a few mutations, can result in startling physical changes and fuel surprisingly rapid evolution.

The Galápagos finches provide a wonderful example of the link between evolution and development. There are at least 14 (some specialists list 15) species of Galápagos finches, distinguished in large measure by their beak structure. The ground finches, for example, have broad, heavy beaks adapted to crushing large, hard seeds. The cactus finches have longer, slender beaks ideal for probing cactus fruits and flowers (Fig. 1). Clifford Tabin and colleagues carefully surveyed a set of genes expressed during avian craniofacial development. They identified a single gene, *Bmp4*, whose expression level correlated with formation of the more robust beaks of

cells — first from mice, then from humans — have been reprogrammed to take on the characteristics of pluripotent stem cells. The reprogramming involves manipulations to get the cells to express at least four transcription factors, Oct4, Sox2, Nanog, and Lin28, all of which are known to help maintain the stem cell–like state. Gradual improvements in this technology may make the harvesting of embryonic stem cells unnecessary and provide a source of stem cells that is genetically matched to a prospective patient.

Our discussion of developmental regulation and stem cells brings us full circle, back to a biochemical beginning. Evolution appropriately provides the first and last words of this book. If evolution is to generate the kind of changes in an organism that would render it a different species, it is the developmental program that must be affected. Developmental and evolutionary processes are closely allied, each informing the other (**Box 28-1**). The continuing study of biochemistry has everything to do with enriching the future of humanity and understanding our origins.

the ground finches. More-robust beaks were also formed in chicken embryos when high levels of Bmp4 were artificially expressed in the appropriate tissues, confirming the importance of *Bmp4*. In a similar study, the formation of long, slender beaks was linked to the expression of calmodulin (see Fig. 12-17) in particular tissues at appropriate developmental stages. Thus, major changes in the shape and function of the beak can be brought about by subtle changes in the expression of just two genes involved in developmental regulation. Very few mutations are required, and the needed mutations affect regulation. New genes are *not* required.

The system of regulatory genes that guides development is remarkably conserved among all vertebrates. Elevated expression of *Bmp4* in the right tissue at the right time leads to more-robust jaw parts in zebrafish. The same gene plays a key role in tooth development in mammals. The development of eyes is triggered by the expression of a single gene, *Pax6*, in fruit flies and in mammals. The mouse *Pax6* gene will trigger the development of fruit fly eyes in the fruit fly, and the fruit fly *Pax6* gene will trigger the development of mouse eyes in the mouse. In each organism, these genes are part of the much larger regulatory cascade that ultimately creates the correct structures in the correct locations in each organism. The cascade is ancient; for example, the *Hox* genes (described in the text) have been part of the developmental program of multicellular eukaryotes for more than 500 million years. Subtle changes in the cascade can have large effects on development, and thus on the ultimate appearance, of the organism. These same subtle changes can fuel remarkably rapid evolution. For example, the 400 to 500 described species of cichlids (spiny-finned fish) in Lake Malawi and Lake Victoria on the African continent are all derived from one or a few populations that colonized each lake in the past 100,000 to 200,000 years. The Galápagos finches simply followed a path of evolution and change that living creatures have been traveling for billions of years.

Low [CaM]: short beak
Early/high [Bmp4]: high beak depth/width

FIGURE 1 Evolution of new beak structures to exploit new food sources. In the Galápagos finches, the different beak structures of the cactus finch and the large ground finch, which feed on different, specialized food sources, were produced to a large extent by a few mutations that altered the timing and level of expression of just two genes: those encoding calmodulin (CaM) and Bmp4. [Information from A. Abzhanov et al., *Nature* 442:563, 2006, Fig. 4.]

SUMMARY 28.3 *Regulation of Gene Expression in Eukaryotes*

- In eukaryotes, large changes in chromatin structure accompany the expression of a gene. Transcriptionally inactive heterochromatin is opened up by chromatin remodeling proteins. These eject, replace, or modify nucleosomes to allow other proteins, mainly RNA polymerase components and regulators, to access sites required to initiate transcription.
- In eukaryotes, positive regulation is more common than negative regulation.
- Promoters for Pol II typically have a TATA box and Inr sequence, as well as multiple binding sites for transcription activators. The latter sites, sometimes located hundreds or thousands of base pairs away from the TATA box, are called upstream activator sequences in yeast and enhancers in higher eukaryotes. To regulate transcriptional activity generally requires large complexes

of proteins. These include basal transcription factors, activators, coactivators, architectural regulators, and the enzymes that modify and remodel chromatin. The effects of transcription activators on Pol II are facilitated by coactivator protein complexes such as Mediator.

- The well-studied yeast genes involved in galactose metabolism provide examples of both positive and negative regulation in a eukaryote.
- The modular structures of the activators have distinct activation and DNA-binding domains.
- Hormones affect the regulation of gene expression in one of two ways. Steroid hormones interact directly with intracellular receptors that are DNA-binding regulatory proteins; binding of the hormone has either positive or negative effects on the transcription of targeted genes.
- Nonsteroid hormones bind to cell surface receptors, triggering a signaling pathway that can lead to phosphorylation of a regulatory protein, affecting its activity.
- Translational regulation is particularly important in eukaryotes. Modulating the translation of an mRNA stored in the cytoplasm affords a more rapid response to cellular challenges than de novo assembly of transcription complexes and mRNA synthesis.
- MicroRNAs (miRNAs) are involved in gene silencing during development and as an antiviral defense. The pathway for processing miRNAs from larger precursors has been harnessed by researchers to develop the gene-silencing technology called RNA interference, or RNAi.
- Regulation mediated by ncRNAs plays an important role in eukaryotic gene expression, with known mechanisms including interactions with proteins, mRNA, and other ncRNAs.
- Development of a multicellular organism presents the most complex regulatory challenge. The fate of cells in the early embryo is determined by establishment of anterior-posterior and dorsal-ventral gradients of proteins that act as transcription activators or translational repressors, regulating the genes required for development of structures appropriate to a particular part of the organism. Sets of regulatory genes operate in temporal and spatial succession, transforming given areas of an egg cell into predictable structures in the adult organism.
- The differentiation of stem cells into functional tissues can be controlled by extracellular signals and conditions.

KEY TERMS

Terms in bold are defined in the glossary.

induction	1054
repression	1054
housekeeping genes	1056
specificity factor	1056
repressor	1056
activator	1056
noncoding RNA (ncRNA)	1056
long noncoding RNA (lncRNA)	1056
operator	1057
negative regulation	1057
positive regulation	1057
architectural regulator	1057
operon	1058
helix-turn-helix	1061
zinc finger	1061
homeodomain	1062
homeobox	1062
RNA recognition motif (RRM)	1062
leucine zipper	1063
basic helix-loop-helix	1064
combinatorial control	1065
cAMP receptor protein (CRP)	1066
regulon	1067
transcription attenuation	1068
translational repressor	1070
stringent response	1071
riboswitch	1072
phase variation	1073
chromatin remodeling	1075
SWI/SNF	1075
histone acetyltransferases (HATs)	1076
enhancers	1078
upstream activator sequences (UASs)	1078
transcription activators	1078
coactivators	1078
basal transcription factors	1078
preinitiation complex (PIC)	1078
high mobility group (HMG)	1079
Mediator	1079
TATA-binding protein (TBP)	1080
hormone response element (HRE)	1083
RNA interference (RNAi)	1086
polarity	1087
metamerism	1087
maternal genes	1087
maternal mRNAs	1087
segmentation genes	1088

PROBLEMS

1. Effect of mRNA and Protein Stability on Regulation *E. coli* cells are growing in a medium with glucose as the sole carbon source. After the sudden addition of tryptophan, the cells continue to grow and divide every 30 min. Describe (qualitatively) how the amount of tryptophan synthase activity in the cells changes with time under each condition:

(a) The *trp* mRNA is stable (degrades slowly over many hours).

(b) The *trp* mRNA degrades rapidly, but tryptophan synthase is stable.

(c) The *trp* mRNA and tryptophan synthase both degrade rapidly.

2. The Lactose Operon A researcher engineers a *lac* operon on a plasmid but inactivates all parts of the *lac* operator (*lacO*) and the *lac* promoter, replacing them with the binding site for the LexA repressor (which acts in the SOS response) and a promoter regulated by LexA. She then introduces the plasmid into *E. coli* cells that have a *lac* operon with an inactive *lacZ* gene. Under what conditions will these transformed cells produce β-galactosidase?

3. Negative Regulation Describe the probable effects on gene expression in the *lac* operon of each mutation:

(a) Mutation in the *lac* operator that deletes most of O_1

(b) Mutation in the *lacI* gene that eliminates binding of repressor to operator

(c) Mutation in the promoter near position –10 that increases its similarity to the *E. coli* consensus sequence
(d) Mutation in the *lacI* gene that eliminates binding of repressor to lactose
(e) Mutation in the promoter near position –10 that decreases its similarity to the *E. coli* consensus sequence

4. Specific DNA Binding by Regulatory Proteins A typical bacterial repressor protein discriminates between its specific DNA-binding site (operator) and nonspecific DNA by a factor of 10^4 to 10^6. About 10 molecules of repressor per cell are sufficient to ensure a high level of repression. Assume that a very similar repressor existed in a human cell, with a similar specificity for its binding site. How many copies of the repressor would a human cell require to elicit a level of repression similar to that in the bacterial cell? (Hint: The *E. coli* genome contains about 4.6 million bp; the human haploid genome has about 3.2 billion bp.)

5. Repressor Concentration in *E. coli* The dissociation constant for a particular repressor-operator complex is very low, about 10^{-13} M. An *E. coli* cell (volume 2×10^{-12} mL) contains 10 copies of the repressor. Calculate the cellular concentration of the repressor protein. How does this value compare with the dissociation constant of the repressor-operator complex? What is the significance of this answer?

6. Catabolite Repression *E. coli* cells are growing in a medium that contains lactose but no glucose. Indicate whether each of the following changes or conditions would increase, decrease, or not change the expression of the *lac* operon. It may be helpful to draw a model depicting what is happening in each situation.
(a) Addition of a high concentration of glucose
(b) A mutation that prevents dissociation of the Lac repressor from the operator
(c) A mutation that completely inactivates β-galactosidase
(d) A mutation that completely inactivates galactoside permease
(e) A mutation that prevents binding of CRP to its binding site near the *lac* promoter

7. Transcription Attenuation How would each manipulation of the leader region of the *trp* mRNA affect transcription of the *E. coli trp* operon?
(a) Increasing the distance (number of bases) between the leader peptide gene and sequence 2
(b) Increasing the distance between sequences 2 and 3
(c) Removing sequence 4
(d) Changing the two Trp codons in the leader peptide gene to His codons
(e) Eliminating the ribosome-binding site for the gene that encodes the leader peptide
(f) Changing several nucleotides in sequence 3 so that it can base-pair with sequence 4 but not with sequence 2

8. Repressors and Repression How would a mutation in the *lexA* gene that prevents autocatalytic cleavage of the LexA protein affect the SOS response in *E. coli*?

9. Regulation by Recombination In the phase variation system of *Salmonella*, what would happen to the cell if the Hin recombinase became more active and promoted recombination (DNA inversion) several times in each cell generation?

10. Initiation of Transcription in Eukaryotes A biochemist discovers a new RNA polymerase activity in crude extracts of cells derived from an exotic fungus. The RNA polymerase initiates transcription only from a single, highly specialized promoter. As the biochemist purifies the polymerase, its activity declines, and the purified enzyme is completely inactive unless he adds crude extract to the reaction mixture. Suggest an explanation for these observations.

11. Functional Domains in Regulatory Proteins A biochemist replaces the DNA-binding domain of the yeast Gal4 protein with the DNA-binding domain from the Lac repressor and finds that the engineered protein no longer regulates transcription of the *GAL* genes in yeast. Draw a diagram of the different functional domains you would expect to find in the Gal4 protein and in the engineered protein. Why does the engineered protein no longer regulate transcription of the *GAL* genes? What might be done to the DNA-binding site recognized by this chimeric protein to make it functional in activating transcription of *GAL* genes?

12. Nucleosome Modification during Transcriptional Activation To prepare genomic regions for transcription, cells acetylate and methylate certain histones in the resident nucleosomes at specific locations. Once transcription is no longer needed, cells need to reverse these modifications. In mammals, peptidylarginine deiminases (PADIs) reverse the methylation of Arg residues in histones. The reaction promoted by these enzymes does not yield unmethylated arginine. Instead, it produces citrulline residues in the histone. What is the other product of the reaction? Suggest a mechanism for this reaction.

13. Gene Repression in Eukaryotes Explain why repression of a eukaryotic gene by an RNA might be more efficient than repression by a protein repressor.

14. Inheritance Mechanisms in Development A *Drosophila* egg that is *bcd*$^-$/*bcd*$^-$ may develop normally, but the adult fruit fly will not be able to produce viable offspring. Explain.

DATA ANALYSIS PROBLEM

15. Engineering a Genetic Toggle Switch in *E. coli* Gene regulation is often described as an "on or off" phenomenon: a gene is either fully expressed or not expressed at all. In fact, repression and activation of a gene involve ligand-binding reactions, so genes can show intermediate levels of expression when intermediate levels of regulatory molecules are present. For example, for the *E. coli lac* operon, consider the binding equilibrium of the Lac repressor, operator DNA, and inducer (see Fig. 28-8). Although this is a complex, cooperative process, it can be approximately modeled by the following reaction (R is repressor; IPTG is the inducer isopropyl-β-D-thiogalactoside):

$$\mathrm{R} + \mathrm{IPTG} \xrightleftharpoons{K_\mathrm{d} = 10^{-4}\,\mathrm{M}} \mathrm{R \cdot IPTG}$$

Free repressor, R, binds to the operator and prevents transcription of the *lac* operon; the R • IPTG complex does not bind to the operator, and thus transcription of the *lac* operon can proceed.
(a) Using Equation 5-8, we can calculate the relative expression level of the proteins of the *lac* operon as a function of [IPTG]. Use this calculation to determine over what range of [IPTG] the expression level would vary from 10% to 90%.
(b) Describe qualitatively the level of *lac* operon proteins present in an *E. coli* cell before, during, and after induction with IPTG. You do not need to give the amounts at exact times—just indicate the general trends.

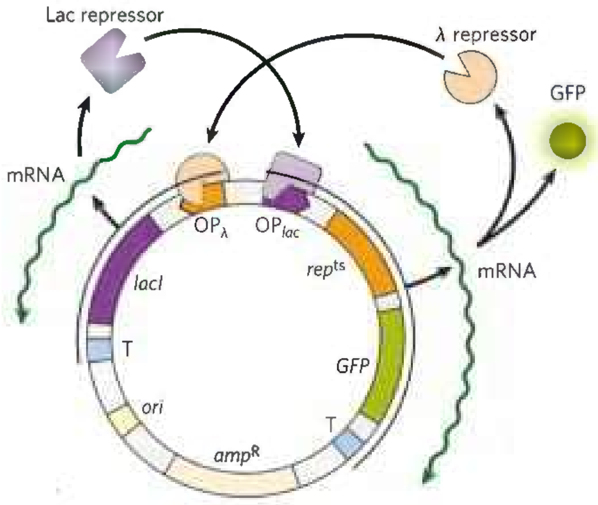
Gardner, Cantor, and Collins (2000) set out to make a "genetic toggle switch"—a gene-regulatory system with two key characteristics, A and B, of a light switch. (A) *It has only two states:* it is either fully on or fully off; it is not a dimmer switch. In biochemical terms, the target gene or gene system (operon) is either fully expressed or not expressed at all; it cannot be expressed at an intermediate level. (B) *Both states are stable:* although you must use a finger to flip the light switch from one state to the other, once you have flipped it and removed your finger, the switch stays in that state. In biochemical terms, exposure to an inducer or some other signal changes the expression state of the gene or operon, and it remains in that state once the signal is removed.

(c) Explain how the *lac* operon lacks both characteristics A and B.

To make their "toggle switch," Gardner and coworkers constructed a plasmid from the following components:

ori	An origin of replication
amp^R	A gene conferring resistance to the antibiotic ampicillin
OP_{lac}	The operator-promoter region of the *E. coli lac* operon
OP_λ	The operator-promoter region of λ phage
lacI	The gene encoding the *lac* repressor protein, LacI. In the absence of IPTG, this protein strongly represses OP_{lac}; in the presence of IPTG, it allows full expression from OP_{lac}.
rep^{ts}	The gene encoding a temperature-sensitive mutant λ repressor protein, rep^{ts}. At 37 °C, this protein strongly represses OP_λ; at 42 °C, it allows full expression from OP_λ.
GFP	The gene for green fluorescent protein (GFP), a highly fluorescent reporter protein (see Fig. 9-16)
T	Transcription terminator

The investigators arranged these components, as shown in the following figure, so that the two promoters were reciprocally repressed: OP_{lac} controlled expression of rep^{ts}, and OP_λ controlled expression of *lacI*. The state of this system was reported by the expression level of *GFP*, which was also under the control of OP_{lac}.



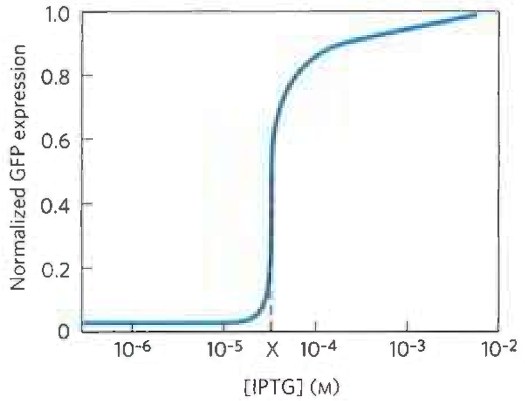
(d) The constructed system has two states: GFP-on (high level of expression) and GFP-off (low level of expression). For each state, describe which proteins are present and which promoters are being expressed.

(e) Treatment with IPTG would be expected to toggle the system from one state to the other. From which state to which? Explain your reasoning.

(f) Treatment with heat (42 °C) would be expected to toggle the system from one state to the other. From which state to which? Explain your reasoning.

(g) Why would this plasmid be expected to have characteristics A and B as described above?

To confirm that their construct did indeed exhibit these characteristics, Gardner and colleagues first showed that, once switched, the GFP expression level (high or low) was stable for long periods of time (characteristic B). Next, they measured the GFP level at different concentrations of the inducer IPTG, with the following results.



They noticed that the average GFP expression level was intermediate at concentration X of IPTG. However, when they measured the GFP expression level *in individual cells* at [IPTG] = X, they found either a high level or a low level of GFP—no cells showed an intermediate level.

(h) Explain how this finding demonstrates that the system has characteristic A. What is happening to cause the bimodal distribution of expression levels at [IPTG] = X?

Abbreviated Solutions to Problems

Fuller solutions to all chapter problems are published in the *Absolute Ultimate Guide to Lehninger Principles of Biochemistry.* For all numerical problems, answers are expressed with the correct number of significant figures.

Chapter 1

1. (a) Diameter of magnified cell = 500 mm **(b)** 36,000 mitochondria **(c)** 3.9×10^{10} glucose molecules

2. (a) 10% **(b)** 5% **(c)** 1.6 mm; 800 times longer than the cell; DNA must be tightly coiled

3. Collect the supernatant from the high-speed centrifugation and centrifuge at a very high speed (150,000 *g*) for 3 hours. The ribosomes will be in the pellet.

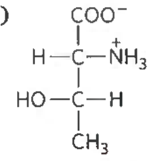
4. (a) Metabolic rate is limited by diffusion, which is limited by surface area. **(b)** 12 μm^{-1} for the bacterium **(c)** Surface-to-volume ratio 300 times higher in the bacterium.

5. 2×10^6 s (about 23 days)

6. The vitamin molecules from the two sources are identical; the body cannot distinguish the source; only associated impurities might vary with the source.

7. (a) COO^-, carboxyl; NH_3, amino; OH, hydroxyl; CH_3, methyl

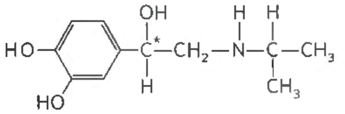
(b)



D-Threonine

(c) 2

8.



The two enantiomers have different interactions with a chiral biological "receptor" (a protein).

9. (a) Fatty acids are more nonpolar than amino acids, which makes them separable on the basis of solubility. The larger size and longer shape of fatty acids could allow separation by some types of chromatography. **(b)** The charge on the phosphate groups of nucleotides could be used to separate them from glucose. The larger size and shape could allow separation by some types of chromatography.

10. Carbon atoms can form linear chains, branched chains, and cyclic structures. It is improbable that silicon could serve as the central organizing element for life, especially in an O_2-containing atmosphere such as that of Earth. Long chains of silicon atoms are not readily synthesized; the polymeric macromolecules necessary for more complex functions would not readily form. Oxygen disrupts bonds between silicon atoms, and silicon-oxygen bonds are extremely stable and difficult to break, preventing the breaking and making of bonds that are essential to life processes.

11. (a) (*R*)-enantiomer: A is COO^-; B is H; C is CH_3. (*S*)-enantiomer: A is CH_3; B is H; C is COO^-. **(b)** It is unnecessary to make enantiomerically pure (*S*)-ibuprofen available because the isomerase converts the less effective enantiomer to the effective enantiomer, but does not catalyze the reverse reaction.

12. (a) 3 Phosphoric acid groups; α-D-ribose; guanine **(b)** Tyrosine; 2 glycines; phenylalanine; methionine **(c)** Choline; phosphoric acid; glycerol; oleic acid; palmitic acid

13. (a) CH_2O; $C_3H_6O_3$

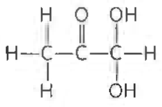
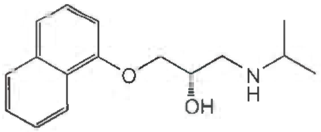
11



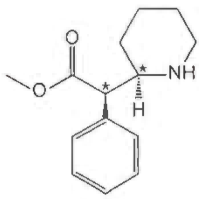
12

(c) X contains a chiral center; eliminates all but **6** and **8**. **(d)** X contains an acidic functional group; eliminates **8**; structure **6** is consistent with all data. **(e)** Structure **6**; we cannot distinguish between the two possible enantiomers.

14. (a) The carbon bearing the hydroxyl group is the chiral carbon. **(b)** The structure shows the (*R*) isomer of propranolol. **(c)** (*S*)-Propranolol has this structure:



15. (a) The chiral carbons are indicated with asterisks. **(b)** The structure shows the (*S,S*) isomer of methylphenidate. **(c)** (*R,R*)-methylphenidate has this structure:



16. Spores are alive because they can transition from a state of being metabolically inert under harsh environmental conditions to an actively growing state when conditions improve. During this transition, spores take in water, which is essential to many biochemical reactions. Germination does not seem to depend on ATP.

17. **(a)** $\Delta G°$ is negative and relatively large. **(b)** There is not enough thermal energy in the wood to overcome the activation energy. **(c)** A match supplies thermal energy to overcome the activation energy barrier. **(d)** The enzyme lowers the activation energy enough for the reaction to occur at room temperature.

18. If this mutation occurs in a coding sequence, it may cause an amino acid substitution during protein synthesis. The consequence to the cell could be anywhere on the spectrum from beneficial, to neutral, to fatal.

19. The resulting protein may fold incorrectly and may not attain its native conformation. Alternatively, the shape of the region that binds with its partner may change, preventing complementary fit. A mutation that malforms an enzyme's active site can destroy the enzyme's catalytic activity.

20. **(a)** The copy begins with already-formed domains with biological activity, so it does not have to evolve from scratch. The copy can undergo mutation without harm to the cell, since the original gene encodes the original product. Alternatively, the copy could undergo mutations that create a lethal product, even though the original gene remains intact. The daughter cell's newly acquired function may be positive or negative. **(b)** Each time a duplicate gene undergoes mutation is an opportunity for the cell to acquire a new, positive trait without risking the loss of function provided by the original gene, which may remain unchanged.

21. Yes, when environmental conditions improve, such as temperature moderation and the availability of water, the animal can rehydrate and recover. That is, biochemical mechanisms exist for restoring the normal state.

22. Mutations may have made DNA repair more efficient. Resistant cells may have developed or increased the ability to synthesize a compound that destroys free radicals. Gene duplication may have provided backup for genes damaged by radiation.

23. **(a)** The enzyme that catalyzes the reaction is a membrane-bound enzyme because the preparation containing only membranes had the largest amount of labeled product. **(b)** The enzyme generated the largest amount of product at pH 7. **(c)** Enzyme activity is slightly higher at pH 8 than at pH 6. **(d)** Magnesium (Mg^{2+}) is effective at activating the system over a range of concentrations. At low concentrations, manganese (Mn^{2+}) is effective at activating the system, but it may inhibit the reaction at higher concentrations. The system shows minimal response to calcium ions (Ca^{2+}). **(e)** The reaction requires CTP, but not GTP, UTP, or ATP. However, the addition of ATP may increase the rate of lecithin synthesis. The ATP from lot 116 was likely contaminated with CTP. **(f)** Phosphocholine + membrane-bound enzyme + Mg^{2+} + CTP $\rightleftharpoons$ lecithin

Chapter 2

1. Weaker; ionic attractive force is proportional to the *inverse* of the dielectric constant, and a hydrophobic "solvent" such as the environment inside the protein has a lower dielectric constant than a polar solvent such as water.

2. Biomolecular interactions generally need to be reversible; weak interactions allow reversibility.

3. Ethanol is polar; ethane is not. The ethanol —OH group can hydrogen-bond with water.

4. **(a)** 4.76 **(b)** 9.19 **(c)** 4.0 **(d)** 4.82

5. **(a)** 1.51×10^{-4} M **(b)** 3.02×10^{-7} M **(c)** 7.76×10^{-12} M

6. 1.1

7. **(a)** $HCl \rightleftharpoons H^+ + Cl^-$ **(b)** 3.3 **(c)** $NaOH \rightleftharpoons Na^+ + OH^-$ **(d)** 9.8

8. 1.1

9. 1.7 nmol of acetylcholine

10. 0.1 M hydrofluoric acid

11. **(a)** strong **(b)** weak **(c)** strong **(d)** strong **(e)** weak **(f)** weak

12. 3.3 mL

13. **(a)** $H_2PO_4^-$ **(b)** HCO_3^- **(c)** CH_3COO^- **(d)** CH_3NH_2

14. **(a)** 5.06 **(b)** 4.28 **(c)** 5.46 **(d)** 4.76 **(e)** 3.76

15. quinoline ion: 0.1 M HCl; *m*-cresol: 0.1 M NaOH; 2-(methylthio)pyridine ion: 0.1 M HCl

16. **(d)** Bicarbonate, a weak base, titrates —OH to —O$^-$, making the compound more polar and more water-soluble.

17. Stomach; the neutral form of aspirin present at the lower pH is less polar and passes through the membrane more easily.

18. 8.8

19. 7.4

20. **(a)** pH 8.6 to 10.6 **(b)** 4/5 **(c)** 10 mL **(d)** pH = $pK_a - 2$

21. 8.9

22. 2.4

23. 6.9

24. 1.4

25. $NaH_2PO_4 \cdot H_2O$, 5.8 g/L; Na_2HPO_4, 8.2 g/L

26. $[A^-]/[HA] = 0.10$

27. Mix 150 mL of 0.10 M sodium acetate and 850 mL of 0.10 M acetic acid.

28. **(a)** pH 3 **(b)** pH 5 **(c)** pH 9 **(d)** pH 9 **(e)** pH 3 **(f)** pH 5. The total buffering region spans approximately 1 pH unit on either side of the pK_a value.

29. **(a)** 4.6 **(b)** 0.1 pH unit **(c)** 4 pH units

30. 4.3

31. 0.13 M acetate and 0.07 M acetic acid

32. 1.8

33. 7

34. **(a)** fully protonated **(b)** zwitterionic **(c)** zwitterionic **(d)** zwitterionic **(e)** fully deprotonated. When the pH is lower than both pK_a values, both the α-amino group and the α-carboxyl group are protonated. When the pH is greater than both pK_a values, neither the α-amino group nor the α-carboxyl group is protonated. When the pH is between the two pK_a values, the α-amino group is protonated, whereas the α-carboxyl group is unprotonated.

35. **(a)** Blood pH is controlled by the carbon dioxide–bicarbonate buffer system, $CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$. During *hypoventilation*, pCO_2 increases in the air space of the lungs and arterial blood, driving the equilibrium to the right, raising $[H^+]$ and lowering blood pH. **(b)** During *hyperventilation*, $[CO_2]$ decreases in the lungs and arterial blood, reducing $[H^+]$ and increasing pH above the normal 7.4 value. **(c)** Lactate is a moderately strong acid, completely dissociating under physiological conditions and thus lowering the pH of blood and muscle tissue. Hyperventilation removes H^+, raising the pH of blood and tissues in anticipation of the acid buildup.

36. 7.4

37. Dissolving more CO_2 in the blood increases $[H^+]$ in blood and extracellular fluids, lowering pH: $CO_2(aq) + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$

38. **(a)** $CH_3—OH < CH_3—CH_2—OH < HO—CH_2CH_2—OH < HO—CH_2CH_2CH_2—OH$ **(b)** number of hydrogen bonds that the compound can form and length of the carbon chain

39. The average bond duration decreases.

40. **(a)** H_2S forms hydrogen bonds with H_2O but not with itself. **(b)** H_2S has a lower boiling point than H_2O. **(c)** No, H_2S is a less polar solvent than H_2O.

41. sodium acetate > sodium propionate > glycine > L-phenylalanine > sodium octanoate

42. $CH_3—(CHOH)—CH_2—CHOH—CH_2—OH > CH_3—(CH_2)_5—OH > CH_3—(CH_2)_{10}—OH$

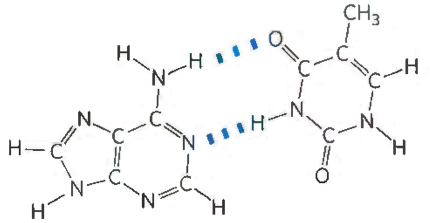
43. (a) HOOC—$(CH_2)_4$—COOH, –2; CH_3—$(CH_2)_4$—COOH, –1; HOOC—$(CH_2)_2$—COOH, –2
(b) HOOC—$(CH_2)_2$—COOH > HOOC—$(CH_2)_4$—COOH > CH_3—$(CH_2)_4$—COOH

44. (a) No, because an effluent of pH 1 would harm the trout and other life in the stream. **(b)** The pH scale runs from very acidic to very alkaline, with the point of neutrality (which is best for living creatures, including trout) midway between 0 and 14. He is proposing to jump out of the frying pan into the fire!

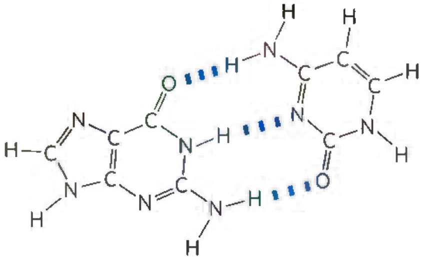
45. pH = 7.6; osmolarity = 0.313 osm/L

46.

(a) Adenine



(b) Guanine



47. (a) Use the substance in its surfactant form to emulsify the spilled oil, collect the emulsified oil, then switch to the nonsurfactant form. The oil and water will separate, and the oil can be collected for further use. **(b)** The equilibrium lies strongly to the right. The stronger acid (lower pK_a), H_2CO_3, donates a proton to the conjugate base of the weaker acid (higher pK_a), amidine. **(c)** The strength of a surfactant depends on the hydrophilicity of its head groups: the more hydrophilic, the more powerful the surfactant. The amidinium form of s-surf is much more hydrophilic than the amidine form, so it is a more powerful surfactant. **(d)** *Point A:* amidinium; the CO_2 has had plenty of time to react with the amidine to produce the amidinium form. *Point B:* amidine; Ar has removed CO_2 from the solution, leaving the amidine form. **(e)** The conductivity rises as uncharged amidine reacts with CO_2 to produce the charged amidinium form. **(f)** The conductivity falls as Ar removes CO_2, shifting the equilibrium to the uncharged amidine form. **(g)** Treat s-surf with CO_2 to produce the surfactant amidinium form, and use this to emulsify the spill. Treat the emulsion with Ar to remove the CO_2 and produce the nonsurfactant amidine form. The oil will separate from the water and can be recovered.

Chapter 3

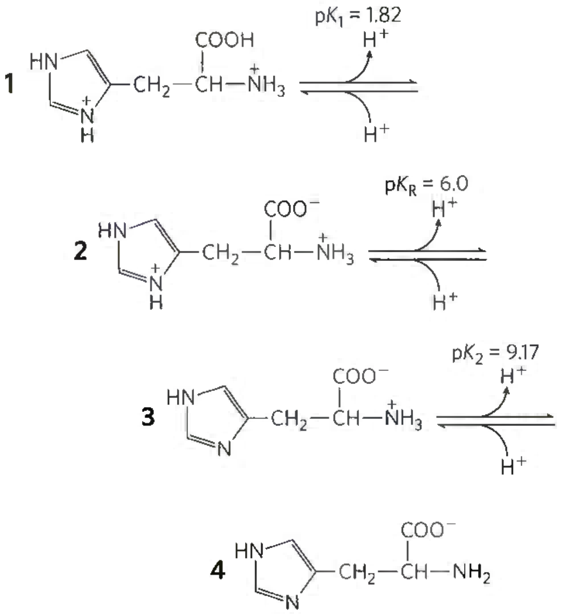
1. The constituents are Glu, Cys, and Gly. The Glu links to the Cys via its γ-carboxyl group.

2. It is L-ornithine, because the amino group occupies the same relative position as the hydroxyl group in L-glyceraldehyde.

3. (a) II **(b)** IV **(c)** I **(d)** III **(e)** II **(f)** II **(g)** IV **(h)** III **(i)** V **(j)** III **(k)** II and IV

4. (a) pI > pK_a of the α-carboxyl group and pI < pK_a of the α-amino group, so both groups are charged (ionized). **(b)** 1 in 2.19×10^7. The pI of alanine is 6.01. From Table 3-1 and the Henderson-Hasselbalch equation, 1 in 4,680 carboxyl groups and 1 in 4,680 amino groups are uncharged. The fraction of alanine molecules with both groups uncharged is 1 in $4{,}680^2$.

5. (a)

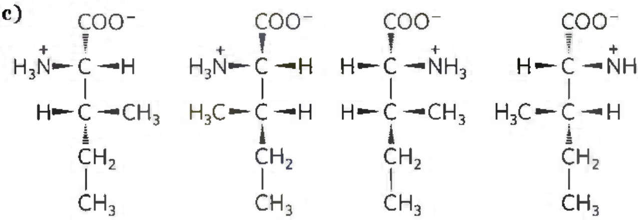


(b), (c)

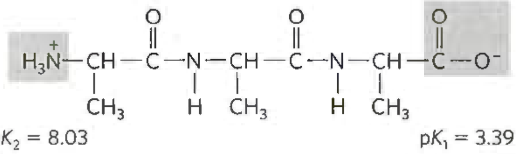
pH	Structure identified in (a)	Net charge	Migrates toward
1	**1**	+2	Cathode
4	**2**	+1	Cathode
8	**3**	0	Does not migrate
12	**4**	–1	Anode

6. (a) Glutamate **(b)** Methionine **(c)** Aspartate **(d)** Glycine **(e)** Serine

7. (a) 2 **(b)** 4
(c)



8. (a) Structure at pH 7:



(b) Electrostatic interaction between the carboxylate anion and the protonated amino group of the alanine zwitterion favorably affects ionization of the carboxyl group. This favorable electrostatic interaction decreases as the length of the poly(Ala) increases, resulting in an increase in pK_1. **(c)** Ionization of the protonated amino group destroys the favorable electrostatic interaction noted in (b). With increasing distance between the charged groups, removal of the proton from the amino group in poly(Ala) becomes easier and thus pK_2 is lower. The intramolecular effects of the amide (peptide bond) linkages keep pK_a values lower than they would be for an alkyl-substituted amine.

9. One H comes from the α-amino group of one amino acid, and an OH is removed from the α-carboxyl group of the amino acid to which the first is joined.

10. 75,000

11. (a) 10,300. The elements of water are lost when a peptide bond forms, so the molecular weight of a Cys residue is not the same as the molecular weight of free cysteine. **(b)** 21

12. The protein has four subunits, with molecular masses of 160, 90, 90, and 60 kDa. The two 90 kDa subunits (possibly identical) are linked by one or more disulfide bonds.

13. (a) at pH 3, +2; at pH 8, 0; at pH 11, –1 **(b)** pI = 7.8

14. Lys, His, Arg; negatively charged phosphate groups in DNA interact with positively charged side groups in histones.

15. (a) $(\text{Glu})_{20}$ **(b)** $(\text{Lys–Val})_3$ **(c)** $(\text{Asn–Ser–His})_5$ **(d)** $(\text{Asn–Ser–His})_5$

16. (a) Specific activity after step 1 is 6.8 units/mg; step 2, 13 units/mg; step 3, 14 units/mg; step 4, 700 units/mg; step 5, 3,500 units/mg; step 6, 5,000 units/mg. **(b)** Step 4 **(c)** Step 3 **(d)** Yes. Specific activity increased only modestly in step 6; SDS polyacrylamide gel electrophoresis.

17. (a) [NaCl] = 0.5 mM **(b)** [NaCl] = 8 μm

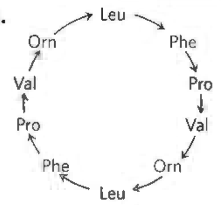
18. B elutes first, A second, C last.

19. The chymotrypsin protein has three distinct polypeptide chains linked by disulfide bonds. They move on the gel as separate species once the disulfide bonds are broken to form the three peptides in lane 2.

20. (a) Amino terminus **(b)** Tyr–Gly–Gly–Phe–Leu

21. Phosphorylation of serine would alter the mass by 80.

22.



The arrows correspond to the orientation of the peptide bonds, —CO → NH—.

23. 75%, 93%. If the efficiency of each amino acid addition is x, then the percentage of full-length peptides with the correct sequence after the addition of seven amino acids will be x^7, as there are *seven* peptide bonds.

24. (a) Y (Tyr) at position 1, F (Phe) at position 7, and R (Arg) at position 9. **(b)** Positions 4 and 9; K (Lys) is more common at 4, R (Arg) is invariant at 9. **(c)** Positions 5 and 10; E (Glu) is more common at both positions. **(d)** Position 2; S (Ser).

25. (a) Anion-exchange chromatography: peptide 2; cation-exchange chromatography: peptide 1; size-exclusion chromatography: peptide 2 **(b)** peptide 3

26. (a) Any linear polypeptide chain has only two kinds of free amino groups: a single α-amino group at the amino terminus, and an ε-amino group on each Lys residue. These amino groups react with FDNB to form a DNP–amino acid derivative. Insulin gave two different α-amino-DNP derivatives, suggesting that it has two amino termini and thus two polypeptide chains—one with an amino-terminal Gly and the other with an amino-terminal Phe. Because the DNP-lysine product is ε-DNP-lysine, the Lys is not at an amino terminus. **(b)** Yes. The A chain has amino-terminal Gly, the B chain has amino-terminal Phe, and (nonterminal) residue 29 in the B chain is Lys. **(c)** Phe–Val–Asp–Glu–. Peptide B1 shows that the amino-terminal residue is Phe. Peptide B2 also includes Val, but since no DNP-Val is formed, Val is not at the amino terminus; it must be on the carboxyl side of Phe. Thus the sequence of B2 is DNP-Phe–Val. Similarly, the sequence of B3 must be DNP-Phe–Val–Asp, and the sequence of the A chain must begin Phe–Val–Asp–Glu–. **(d)** No. The known amino-terminal sequence of the A chain is Phe–Val–Asn–Gln–. The Asn and Gln appear in Sanger's analysis as Asp and Glu because the vigorous hydrolysis in step 7 hydrolyzed the amide bonds in Asn and Gln (as well as the peptide bonds), forming Asp and Glu. Sanger et al. could not distinguish Asp from Asn or Glu from Gln at this stage in their analysis. **(e)** The sequence exactly matches that in Fig. 3-24. Each peptide in the table gives specific information about which Asx residues are Asn or Asp and which Glx residues are Glu or Gln.

Ac1: residues 20–21. This is the only Cys–Asx sequence in the A chain; there is ~1 amido group in this peptide, so it must be Cys–Asn:

N–Gly–Ile–Val–Glx–Glx–Cys–Cys–Ala–Ser–Val–
1 5 10
Cys–Ser–Leu–Tyr–Glx–Leu–Glx–Asx–Tyr–Cys–**Asn**–*C*
15 20

Ap15: residues 14–15–16. This is the only Tyr–Glx–Leu sequence in the A chain; there is ~1 amido group, so the peptide must be Tyr–Gln–Leu:

N–Gly–Ile–Val–Glx–Glx–Cys–Cys–Ala–Ser–Val–
1 5 10
Cys–Ser–Leu–Tyr–**Gln**–Leu–Glx–Asx–Tyr–Cys–Asn–*C*
15 20

Ap14: residues 14–15–16–17. There is ~1 amido group, and we already know that residue 15 is Gln, so residue 17 must be Glu:

N–Gly–Ile–Val–Glx–Glx–Cys–Cys–Ala–Ser–Val–
1 5 10
Cys–Ser–Leu–Tyr–Gln–Leu–**Glu**–Asx–Tyr–Cys–Asn–*C*
15 20

Ap3: residues 18–19–20–21. There are ~2 amido groups, and we know that residue 21 is Asn, so residue 18 must be Asn:

N–Gly–Ile–Val–Glx–Glx–Cys–Cys–Ala–Ser–Val–
1 5 10
Cys–Ser–Leu–Tyr–Gln–Leu–Glu–**Asn**–Tyr–Cys–Asn–*C*
15 20

Ap1: residues 17–18–19–20–21, which is consistent with residues 18 and 21 being Asn.

Ap5pa1: residues 1–2–3–4. There are ~0 amido groups, so residue 4 must be Glu:

N–Gly–Ile–Val–**Glu**–Glx–Cys–Cys–Ala–Ser–Val–
1 5 10
Cys–Ser–Leu–Tyr–Gln–Leu–Glu–Asn–Tyr–Cys–Asn–*C*
15 20

Ap5: residues 1 through 13. There is ~1 amido group, and we know that residue 4 is Glu, so residue 5 must be Gln:

N–Gly–Ile–Val–Glu–**Gln**–Cys–Cys–Ala–Ser–Val–
1 5 10
Cys–Ser–Leu–Tyr–Gln–Leu–Glu–Asn–Tyr–Cys–Asn–*C*
15 20

Chapter 4

1. (a) Shorter bonds have a higher bond order (are multiple rather than single) and are stronger. The peptide C—N bond is stronger than a single bond and is midway between a single bond and a double bond in character. **(b)** Rotation about the peptide bond is difficult at physiological temperatures because of its partial double-bond character.

2. (a) The principal structural units in the wool fiber polypeptide (α-keratin) are successive turns of the α helix, at 5.4 Å intervals; coiled coils produce the 5.2 Å spacing. Steaming and stretching the fiber yields an extended polypeptide chain with the β conformation, with a distance between adjacent R groups of about

7.0 Å. As the polypeptide reassumes an α-helical structure, the fiber shortens. **(b)** Wool shrinks in the presence of moist heat, as polypeptide chains are converted from an extended β conformation to the native α-helix conformation. The structure of silk—β sheets, with their small, closely packed amino acid side chains—is more stable than that of wool.

3. ~42 peptide bonds per second

4. At pH > 6, the carboxyl groups of poly(Glu) are deprotonated; repulsion among negatively charged carboxylate groups leads to unfolding. Similarly, at pH 7, the amino groups of poly(Lys) are protonated; repulsion among these positively charged groups also leads to unfolding.

5. (a) Disulfide bonds are covalent bonds, which are much stronger than the noncovalent interactions that stabilize most proteins. They cross-link protein chains, increasing their stiffness, mechanical strength, and hardness. **(b)** Cystine residues (disulfide bonds) prevent the complete unfolding of the protein.

6. ϕ = (f) and ψ = (e)

7. (a) Bends are most likely at residues 7 and 19; Pro residues in the cis configuration accommodate turns well. **(b)** The Cys residues at positions 13 and 24 can form disulfide bonds. **(c)** External surface: polar and charged residues (Asp, Gln, Lys); interior: nonpolar and aliphatic residues (Ala, Ile); Thr, though polar, has a hydropathy index near zero and thus can be found either on the external surface or in the interior of the protein.

8. (a) At pH 6.0, the amino acid residues are in the correct protonation state to form an ion pair. At pH 2.0, both Asp and His are predominantly protonated, and at pH 10.0, they are both predominantly deprotonated. **(b)** Burial of a charged amino acid residue will destabilize the protein and shift the thermal denaturation curve to lower temperatures. **(c)** Lesser. At pH 10.0, a greater fraction of the Lys side chain will be deprotonated and uncharged, facilitating its burial in a hydrophobic environment.

9. 30 amino acid residues; 0.87

10. For many proteins, the amino acid sequence dictates the formation of a unique, folded structure. However, the reverse is not true. Many different amino acid sequences can give rise to similar folded structures. For example, the relative orientation of the charged amino acid residues in an ion pair can be switched while still preserving the overall location of the interaction.

11. Protein (a), a β barrel, is described by Ramachandran plot (c), which shows most of the allowable conformations in the upper left quadrant where the bond angles characteristic of the β conformation are concentrated. Protein (b), a series of α helices, is described by plot (d), where most of the allowable conformations are in the lower left quadrant.

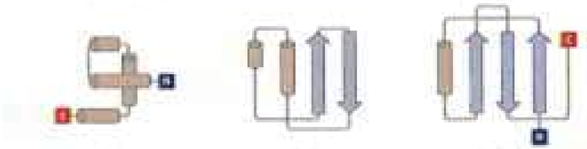
12. (a) The number of moles of DNP-valine formed per mole of protein equals the number of amino termini and thus the number of polypeptide chains. **(b)** 4 **(c)** Different chains would probably run as discrete bands on an SDS polyacrylamide gel.

13. (a) Aromatic residues seem to play an important role in stabilizing amyloid fibrils. Thus, molecules with aromatic substituents may inhibit amyloid formation by interfering with the stacking or association of the aromatic side chains. **(b)** Amyloid forms in the pancreas in association with type 2 diabetes, and forms in the brain in Alzheimer disease. Although the amyloid fibrils in the two diseases involve different proteins, the fundamental structure of the amyloid is similar and is similarly stabilized in both, so they are potential targets for similar drugs designed to disrupt this structure.

14. Although a protein may have only one unique folded structure, many different unfolded structures may exist. The different folding pathways and structures used by the product of other disease alleles of CFTR may not be corrected by lumacaftor.

15. (a) x-ray crystallography **(b)** cryo-EM **(c)** NMR **(d)** NMR or CD

16. (a) 2QYC is B; 2BNH is C; 2Q5R is E or M; 1XU9 is H; 3H7X is I; 1OU5 is E or M; 2WCD is O. **(b)** dimer, α/β; monomer, α/β; dimer, α/β; tetramer, α/β; trimer, all α; dimer, α/β; 24-mer or double dodecamer (12-mer), all α. **(c)** BIOCHEM



(a) (b) (c)

17. (a) NFκB transcription factor, also called RelA transforming factor **(b)** No. You will obtain similar results, but with additional related proteins listed. **(c)** The protein has two subunits. There are multiple variants of the subunits, with the best characterized being 50, 52, or 65 kDa. These pair with each other to form a variety of homodimers and heterodimers. The structures of a number of different variants can be found in the PDB. **(d)** The NFκB transcription factor is a dimeric protein that binds specific DNA sequences, enhancing transcription of nearby genes. One such gene is the immunoglobulin κ (kappa) light chain, from which the transcription factor gets its name.

18. (a) Aba is a suitable replacement because Aba and Cys have side chains that are approximately the same size and are similarly hydrophobic. However, Aba cannot form disulfide bonds, so it will not be a suitable replacement if these are required. **(b)** There are many important differences between the synthesized protein and HIV protease produced by a human cell, any of which could result in an inactive synthetic enzyme. (1) Although Aba and Cys have a similar size and hydrophobicity, Aba may not be similar enough for the protein to fold properly. (2) HIV protease may require disulfide bonds for proper functioning. (3) Many proteins synthesized by ribosomes fold while being produced; the protein in this study folded only after the chain was complete. (4) Proteins synthesized by ribosomes may interact with the ribosomes as they fold; this is not possible for the protein in the study. (5) Cytosol is a more complex solution than the buffer used in the study; some proteins may require specific, unknown proteins for proper folding. (6) Proteins synthesized in cells often require chaperones for proper folding; these are not present in the study buffer. (7) In cells, HIV protease is synthesized as part of a larger chain that is then proteolytically processed; the protein in the study was synthesized as a single molecule. **(c)** Because the enzyme *is* functional when Aba is substituted for Cys, disulfide bonds do not play an important role in the structure of HIV protease. **(d)** *Model 1:* It would fold like the L-protease. *For:* The covalent structure is the same (except for chirality), so it should fold like the L-protease. *Against:* Chirality is not a trivial detail; three-dimensional shape is a key feature of biological molecules. The synthetic enzyme will not fold like the L-protease. *Model 2:* It would fold to the mirror image of the L-protease. *For:* Because the individual components are mirror images of those in the biological protein, it will fold in the mirror-image shape. *Against:* The interactions involved in protein folding are very complex, so the synthetic protein will most likely fold in another form. *Model 3:* It would fold to something else. *For:* The interactions involved in protein folding are very complex, so the synthetic protein will most likely fold in another form. *Against:* Because the individual components are mirror images of those in the biological protein, it will fold in the mirror-image shape. **(e)** *Model 2.* The enzyme is active, but with the enantiomeric form of the biological substrate, and it is inhibited by the enantiomeric form of the biological inhibitor. This is consistent with the D-protease being the mirror image of the L-protease. **(f)** Evans blue is achiral; it binds to both forms of the enzyme. **(g)** No. Because proteases contain only L-amino acids and recognize only L-peptides, chymotrypsin would not digest the D-protease. **(h)** Not necessarily. Depending on the individual enzyme, any of the problems listed in (b) could result in an inactive enzyme.

Chapter 5

1. Protein B has a higher affinity for ligand X; its lower K_d indicates that protein B will be half-saturated at a much lower concentration of X than will protein A. Protein A has $K_a = 3.3 \times 10^6 \text{M}^{-1}$; protein B has $K_a = 2.5 \times 10^7 \text{M}^{-1}$.

2. (a) $n_H < 1.0$ can mean that the protein exhibits negative cooperativity, where the binding of one ligand to the protein decreases its affinity for other ligand molecules. **(b), (c)** There are some instances where $n_H < 1.0$ occurs without true negative cooperativity. For example, $n_H < 1.0$ could also occur if a single polypeptide contained multiple binding sites that had a different affinity for the ligand. If a protein preparation contains a heterogeneous mixture of the protein where some molecules are partially denatured, the measured binding affinity would be artificially decreased, resulting in $n_H < 1.0$. **(d)** If a protein has multiple ligand binding sites that all have the same binding affinity and do not affect one another, no cooperativity, positive or negative, will be observed.

3. $k_d = 8.9 \times 10^{-5} \text{s}^{-1}$

4. (a) 33 nM, **(b)** 0.15 μM, **(c)** 1.9 μM

5. (a) $K_d = 4.0$ nM (shortcut: the K_d is equivalent to the ligand concentration where $Y = 0.5$). **(b)** The rat receptor has the highest affinity, as it has the lowest K_d.

6. Tight binding of CO to a few binding sites in a hemoglobin tetramer tends to force the entire protein into the R state. O_2 can still bind to the unoccupied sites, but it will bind tightly and not be released into the tissues.

7. The cooperative behavior of hemoglobin arises from subunit interactions.

8. (a) Shift the curve to the right. **(b)** Shift the curve to the right. **(c)** Shift the curve to the right. All of these conditions would decrease the affinity of hemoglobin for O_2.

9. (a) The observation that HbA (maternal) is about 60% saturated when the pO_2 is 4 kPa, whereas HbF (fetal) is more than 90% saturated under the same physiological conditions, indicates that HbF has a higher O_2 affinity than HbA. **(b)** The higher O_2 affinity of HbF ensures that oxygen will flow from maternal blood to fetal blood in the placenta. Fetal blood approaches full saturation where the O_2 affinity of HbA is low. **(c)** The observation that the O_2-saturation curve of HbA undergoes a larger shift on BPG binding than that of HbF suggests that HbA binds BPG more tightly than does HbF. Differential binding of BPG to the two hemoglobins may determine the difference in their O_2 affinities.

10. (a) Hb Memphis **(b)** HbS, Hb Milwaukee, Hb Providence, and possibly Hb Cowtown **(c)** Hb Providence

11. More tightly. An inability to form tetramers would limit the cooperativity of these variants, and the binding curve would become more hyperbolic. Also, the BPG-binding site would be disrupted. Oxygen binding would probably be tighter, because the default state in the absence of bound BPG is the tight-binding R state.

12. (a) 3.3×10^{-8} M **(b)** 5×10^{-8} M **(c)** 2×10^{-7} M **(d)** 4.5×10^{-7} M. Note that a rearrangement of Eqn 5-8 gives $[L] = YK_d/(1 - Y)$.

13. The epitope is likely to be a structure that is buried when G-actin polymerizes to form F-actin.

14. (a) The human immune system requires several days to mount a staged response to antigens on the surface of a pathogen. Both trypanosomes and HIV evade the immune system by altering the surface proteins to which immune system components initially bind. Thus, the host organism regularly faces new antigens and requires time to mount an immune response to each one, giving the pathogen time to replicate and spread. HIV also evades the immune system by actively infecting and destroying immune system cells—namely, helper T cells (T_H cells).

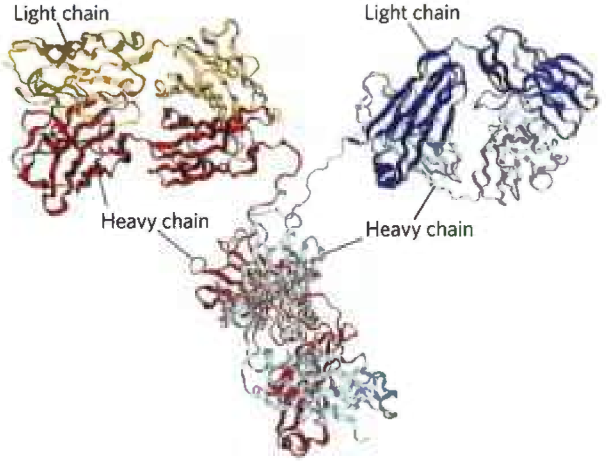
15. Binding of ATP to myosin triggers dissociation of myosin from the actin thin filament. In the absence of ATP, actin and myosin bind tightly to each other.

16. (a) 2 **(b)** 3 **(c)** 1 **(d)** 4

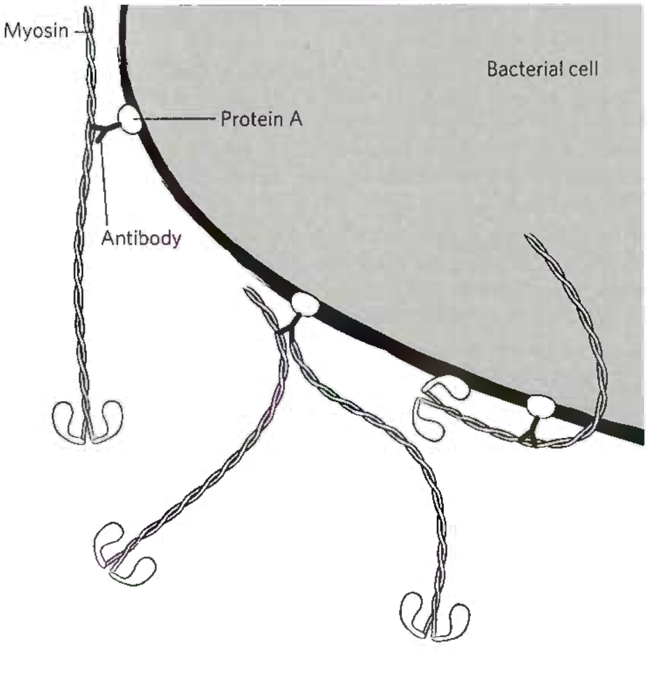
17. (a) Chain L is the light chain and chain H is the heavy chain of the Fab fragment. Chain Y is lysozyme. **(b)** β conformation structures are predominant in the variable and constant regions of the fragment. **(c)** Fab heavy-chain fragment: 218 amino acid residues; light-chain fragment: 214; lysozyme: 129. Less than 15% of the lysozyme molecule is in contact with the Fab fragment. **(d)** Residues that seem to be in contact with lysozyme include, in the H chain: Gly^{31}, Tyr^{32}, Arg^{99}, Asp^{100}, and Tyr^{101}; in the L chain: Tyr^{32}, Tyr^{49}, Tyr^{50}, and Trp^{92}. In lysozyme, residues Asn^{19}, Gly^{22}, Tyr^{23}, Ser^{24}, Lys^{116}, Gly^{117}, Thr^{118}, Asp^{119}, Gln^{121}, and Arg^{125} seem to be situated at the antigen-antibody interface. Not all of these residues are adjacent in the primary structure. Folding of the polypeptide into higher levels of structure brings nonconsecutive residues together to form the antigen-binding site.

18. (a) 2 **(b)** Instantly. Suitable antibodies are almost always present before any challenge from the virus. **(c)** >100,000,000

(d)



19. (a)



The drawing is not to scale; any given cell would have many more myosin molecules on its surface. **(b)** ATP is needed to provide the chemical energy to drive the motion (see Chapter 13). **(c)** An antibody that bound to the myosin tail, the actin-binding site, would block actin binding and prevent movement. An antibody that bound to actin would also prevent actin-myosin interaction and thus movement. **(d)** There are two possible explanations: (1) Trypsin cleaves only at Lys and Arg residues (see Table 3-6), so would not cleave at many sites in the protein. (2) Not all Arg or Lys residues are equally accessible to trypsin; the most-exposed sites would be cleaved first. **(e)** The S1 model. The hinge model predicts that bead-antibody-HMM complexes (with the hinge) would move, but bead-antibody-SHMM complexes (no hinge) would not. The S1 model predicts that because both complexes include S1, both would move. The finding that the beads move with SHMM (no hinge) is consistent only with the S1 model. **(f)** With fewer myosin molecules bound, the beads could temporarily fall off the actin as a myosin let go of it. The beads would then move more slowly, as time is required for a second myosin to bind. At higher myosin density, as one myosin lets go, another quickly binds, leading to faster motion. **(g)** Above a certain density, what limits the rate of movement is the intrinsic speed with which myosin molecules move the beads. The myosin molecules are moving at a maximum rate; adding more will not increase speed.

Chapter 6

1. The activity of the enzyme that converts sugar to starch is destroyed by heat denaturation.

2. 2.4×10^{-6} M

3. 9.5×10^{8} years

4. The enzyme-substrate complex is more stable than the enzyme alone.

5. The reaction rate can be measured by following the decrease in absorption by NADH (at 340 nm) as the reaction proceeds. Determine the K_m value; using substrate concentrations well above the K_m, measure initial rate (rate of NADH disappearance with time, measured spectrophotometrically) at several known enzyme concentrations, and plot initial rate versus concentration of enzyme. The plot should be linear, with a slope that provides a measure of LDH concentration.

6. (a), (c), (e)

7. **(a)** 1.7×10^{-3} M **(b)** 0.33, 0.67, 0.91 **(c)** The red curve corresponds to enzyme B ([X] > K_m for this enzyme); the black curve, to enzyme A.

8. **(a)** 0.2 $\mu\text{M s}^{-1}$ **(b)** 0.6 $\mu\text{M s}^{-1}$ **(c)** 0.9 $\mu\text{M s}^{-1}$

9. **(a)** 2,000 s^{-1} **(b)** Measured $V_{max} = 1\ \mu\text{M s}^{-1}$; $K_m = 2\ \mu\text{M}$

10. **(a)** 400 s^{-1} **(b)** 10 μM **(c)** $\alpha = 2, \alpha' = 3$ **(d)** Mixed inhibitor

11. **(a)** 24 nM **(b)** 4 μM (V_0 is exactly one-half V_{max}, so [X] = K_m) **(c)** 40 μM (V_0 is exactly one-half V_{max}, so [X] = 10 times K_m in the presence of inhibitor) **(d)** No. $k_{cat}/K_m = (0.33\ \text{s}^{-1})/(4 \times 10^{-6}\ \text{M}) = 8.25 \times 10^{4}\ \text{M}^{-1}\ \text{s}^{-1}$, well below the diffusion-controlled limit.

12. $V_{max} \approx 140\ \mu\text{M/min}$; $K_m \approx 1 \times 10^{-5}$ M

13. **(a)** $V_{max} = 51.5$ mM/min; $K_m = 0.59$ mM **(b)** Competitive inhibition

14. $V_{max} = 0.50\ \mu\text{mol/min}$; $K_m = 2.2$ mM

15. **(a)** A; **(b)** B

16. $2.0 \times 10^{7}\ \text{min}^{-1}$

17. **(a)** P **(b)** Q **(c)** E **(d)** B **(e)** A **(f)** F

18. **(a)** Increase **(b)** Decrease **(c)** No change **(d)** No change

19. The basic assumptions of the Michaelis-Menten equation still hold. The reaction is at steady state, and the rate is determined by $V_0 = k_2[\text{ES}]$. The equations needed to solve for [ES] are

$$[\text{E}_t] = [\text{E}] + [\text{ES}] + [\text{EI}] \quad \text{and} \quad [\text{EI}] = \frac{[\text{E}][\text{I}]}{K_I}$$

[E] can be obtained by rearranging Eqn 6-19. The rest follows the pattern of the Michaelis-Menten equation derivation in the text.

20. 29,000. The calculation assumes that there is only one essential Cys residue per enzyme molecule.

21. Activity of the prostate enzyme equals total phosphatase activity in a blood sample minus phosphatase activity in the presence of enough tartrate to completely inhibit the prostate enzyme.

22. The inhibition is mixed. Because K_m seems not to change appreciably, this could be the special case of mixed inhibition called noncompetitive.

23. Apparent $K_m = \alpha K_m/\alpha'$. The [S] at which $V_0 = V_{max}/2\alpha'$ is obtained when all terms except V_{max} on the right side of Eqn 6-30—that is, $[\text{S}]/(\alpha K_m + \alpha'[\text{S}])$—equal $\alpha'/2$. Begin with $[\text{S}]/(\alpha K_m + \alpha'[\text{S}]) = \alpha'/2$ and solve for [S].

24. An amino acid with a positively charged side chain, such as Lys, His, or Arg, could pull electron density away from Tyr.

25. At pH 5.2, Glu^{35} is protonated and neutral and Asp^{52} is unprotonated and negatively charged. The optimum activity occurs when Glu^{35} is protonated and Asp^{52} is unprotonated. Optimal activity requires that Glu^{35} be protonated and Asp^{52} be unprotonated. Activity thus declines with decreasing pH as Asp^{52} is protonated, and with increasing pH as Glu^{35} is unprotonated.

26. **(a)** Although it can be ionized, the sulfhydryl group is relatively nonpolar (see Chapter 3). Amino butyric acid has a nonpolar side chain of similar size to the Cys side chain. **(b)** Because the peptide is made up of D-amino acids, the same shape is unlikely. A mirror image shape is likely, as the D-amino acids are mirror images of their L-stereoisomers. Prior to testing, a completely inactive form is at least plausible. **(c)** The mirror image hypothesis is strongly supported. The substrates and inhibitors made up of D-amino acids are uniquely active. **(d)** No. The active site of chymotrypsin is configured to act on peptides made up of L-amino acids. **(e)** No. The folding process is complex, and sometimes requires assistance from chaperones and specialized enzymes. Some enzymes and proteins can fold spontaneously into an active protein, but others cannot.

Chapter 7

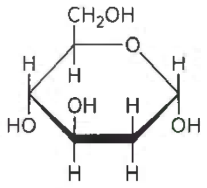
1. With reduction of the carbonyl oxygen to a hydroxyl group, the chemistry at C-1 and C-3 is the same; the glycerol molecule is not chiral.

2. Epimers differ by the configuration about only *one* carbon.
(a) D-altrose (C-2), D-glucose (C-3), D-gulose (C-4)
(b) D-idose (C-2), D-galactose (C-3), D-allose (C-4)
(c) D-arabinose (C-2), D-xylose (C-3)

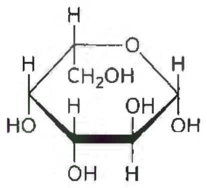
3. To convert α-D-glucose to β-D-glucose, the bond between C-1 and the hydroxyl on C-5 (as in Fig. 7-6) must be broken; to convert D-glucose to D-mannose, either the —H or —OH bond on C-2 must be broken. Conversion between chair conformations does not require bond breakage; this is the critical distinction between configuration and conformation.

4. **(a)** Both are polymers of D-glucose, but they differ in the glycosidic linkage: (β1→4) for cellulose, (α1→4) for glycogen. **(b)** Both are hexoses, but glucose is an aldohexose, fructose a ketohexose. **(c)** Both are disaccharides, but maltose has two (α1→4)-linked D-glucose units, and sucrose has (α1↔2β)-linked D-glucose and D-fructose.

5.

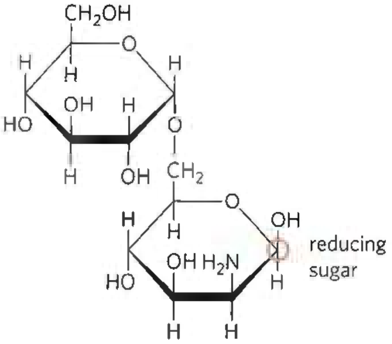


α-D-Mannose



β-L-Galactose

6.



7. An individual with a condition that increases the rate of erythrocyte destruction and turnover would be expected to exhibit less hemoglobin glycation (a lower HbA1c value) because of the shorter-than-normal exposure of the hemoglobin to glucose.

8. A hemiacetal forms when an aldose or a ketose condenses with an alcohol; a glycoside forms when a hemiacetal condenses with an alcohol (see Fig. 7-5).

9. Fructose cyclizes to either the pyranose structure or the furanose structure. Increasing the temperature shifts the equilibrium in the direction of the furanose, the less-sweet form.

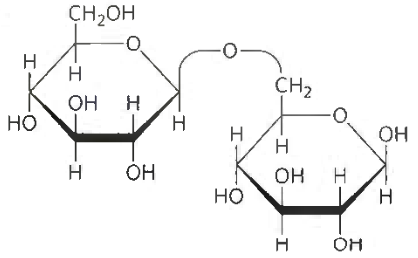
10. In 6-phosphogluconolactone, C-1 is a carboxylic acid ester; in glucose, C-1 is a hemiacetal.

11. Boiling a solution of sucrose in water hydrolyzes some of the sucrose to invert sugar. Hydrolysis is accelerated and occurs at lower temperatures with the addition of a small amount of acid (lemon juice or cream of tartar, for example).

12. Prepare a slurry of sucrose and water for the core; add a small amount of sucrase (invertase); immediately coat with chocolate.

13. Sucrose has no free anomeric carbon to undergo mutarotation.

14.



Yes; yes

15. *N*-Acetyl-*β*-D-glucosamine is a reducing sugar; its C-1 can be oxidized (p. 237). D-Gluconate is not a reducing sugar; its C-1 is already at the oxidation state of a carboxylic acid. GlcN(*α*1↔1*α*)Glc is not a reducing sugar; the anomeric carbons of both monosaccharides are involved in the glycosidic bond.

16. Native cellulose consists of glucose units linked by (*β*1→4) glycosidic bonds, which force the polymer chain into an extended conformation. Parallel series of these extended chains form intermolecular hydrogen bonds, aggregating into long, tough, insoluble fibers. Glycogen consists of glucose units linked by (*α*1→4) glycosidic bonds, which cause bends in the chain and prevent formation of long fibers. In addition, glycogen is highly branched and, because many of its hydroxyl groups are exposed to water, is highly hydrated and disperses in water.

Cellulose is a structural material in plants, consistent with its side-by-side aggregation into insoluble fibers. Glycogen is a storage fuel in animals. Highly hydrated glycogen granules with their many nonreducing ends can be rapidly hydrolyzed by glycogen phosphorylase to release glucose 1-phosphate.

17. Cellulose is several times longer; it assumes an extended conformation, whereas amylose has a helical structure.

18. 7×10^3 residues/s

19. Glycoproteins: b, c, f; proteoglycans: a, d, e

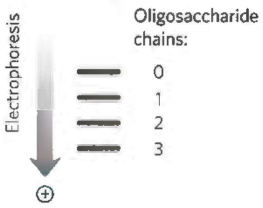
20. The ball-and-stick models of the disaccharide in Fig. 7-16 show no steric interactions, but space-filling models, showing atoms with their correct relative sizes, would show several strong steric hindrances in the high-energy conformer that are not present in the extended conformer.

21. The negative charges on chondroitin sulfate repel each other and force the molecule into an extended conformation. The polar molecule attracts many water molecules, increasing the molecular volume. In the dehydrated solid, each negative charge is counterbalanced by a positive ion, and the molecule condenses.

22. Positively charged amino acid residues would bind the highly negatively charged groups on heparin. In fact, Lys residues of antithrombin III interact with heparin.

23. The order of the hexoses (ABC, ACB, etc.), the stereochemistry at each of two anomeric carbons (*α* or *β*), and the carbon atoms involved in each glycosidic linkage ((1→4), (1→6), (3→4), etc.)

24.



25. Oligosaccharides; their subunits can be combined in more ways than the amino acid subunits of oligopeptides. Each hydroxyl group can participate in glycosidic bonds, and the configuration of each glycosidic bond can be either *α* or *β*. The polymer can be linear or branched.

26. Administer an oligosaccharide with the same structure as that recognized by ricin, or high concentrations of *N*-acetylgalactosamine itself. Ricin will bind the free oligosaccharide or acetylgalactosamine instead of the cell surface target, preventing the entry of the toxin.

27. (a) Branch-point residues yield 2,3-di-*O*-methylglucose; unbranched residues yield 2,3,6-tri-*O*-methylglucose. **(b)** 3.75%

28. (a) The tests involve trying to dissolve only part of the sample in a variety of solvents, then analyzing both dissolved and undissolved materials to see whether their compositions differ. **(b)** For a pure substance, all molecules are the same and any dissolved fraction will have the same composition as any undissolved fraction. An impure substance is a mixture of more than one compound. When the sample is treated with a particular solvent, more of one component may dissolve, leaving more of the other component(s) behind. As a result, the dissolved and undissolved fractions will have different compositions. **(c)** A quantitative assay allows researchers to be sure that none of the activity has been lost through degradation. When the structure of a molecule is being determined, it is important that the sample under analysis consist only of intact (undegraded) molecules. If the sample is contaminated with degraded material, this will give confusing and perhaps uninterpretable structural results. A qualitative assay would detect the presence of activity, even if the sample had become significantly degraded. **(d)** Results 1 and 2. Result 1 is consistent with the known structure, because type B antigen has three molecules of galactose; types A and O each have only two. Result 2 is also consistent, because type A has two amino sugars (*N*-acetylgalactosamine and *N*-acetylglucosamine); types B and O have only one (*N*-acetylglucosamine). Result 3 is *not* consistent with the known structure: for type A, the glucosamine:galactosamine ratio is 1:1; for type B, it is 1:0. **(e)** The samples were probably impure and/or partly degraded. The first two results were correct possibly because the method was only roughly quantitative and thus not as sensitive to inaccuracies in measurement. The third result is more quantitative and thus more likely to differ from predicted values because of impure or degraded samples. **(f)** An exoglycosidase. If it were an endoglycosidase, one of the products of its action on O antigen would include galactose, *N*-acetylglucosamine, or *N*-acetylgalactosamine, and at least one of those sugars would be able to inhibit the degradation. Given that the enzyme is not inhibited by any of these sugars, it must be an exoglycosidase, removing only the terminal sugar from the chain. The terminal sugar of O antigen is fucose, so fucose is the only sugar that could inhibit the degradation of O antigen. **(g)** The exoglycosidase removes *N*-acetylgalactosamine from A antigen and galactose from B antigen. Because fucose is not a product of either reaction, it will not prevent removal of these sugars, and the resulting substances will no longer be active as A antigen or as B antigen. However, the products should be active as O antigen, because degradation stops at fucose. **(h)** All the results are consistent with Fig. 10-13. (1) D-Fucose and L-galactose, which would protect against degradation, are not present in any of the antigens. (2) The terminal sugar of A antigen is *N*-acetylgalactosamine, and this sugar alone protects this antigen from degradation. (3) The terminal sugar of B antigen is galactose, which is the only sugar capable of protecting this antigen.

Chapter 8

1. N-3 and N-7

2. (5′)GCGCAATATTTTGAGAAATATTGCGC(3′); it contains a palindrome. The individual strands can form hairpin structures; the two strands can form a cruciform.

3. 9.4×10^{17}

4. (a) Deoxyadenylate, deoxy-O^6-methylguanylate, an apurinic site (or AP site or abasic site), deoxyuridylate **(b)** 5′ end at upper left and 3′ end at lower right **(c)** The tetranucleotide is DNA, as it is made up of deoxynucleotides. This is true despite the presence of a uracil base.

5. Helices in RNA hairpins assume an A conformation; helices in DNA hairpins generally assume a B conformation.

6. In eukaryotic DNA, about 5% of C residues are methylated. 5-Methylcytosine can spontaneously deaminate to form thymine; the resulting G–T pair is one of the most common mismatches in eukaryotic cells.

7. Higher

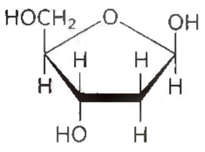
8. Without the base, the ribose ring can be opened to generate the noncyclic aldehyde form. This, and the loss of base-stacking interactions, could contribute significant flexibility to the DNA backbone.

9. CGCGCGTGCGCGCGCG

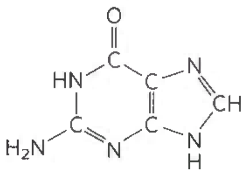
10. RNA nucleotides have a 2′-hydroxyl group on the pentose ring, and the common pyrimidine bases for RNA nucleotides are uracil and cytosine.

11. Base stacking in nucleic acids tends to reduce the absorption of UV light. Denaturation involves loss of base stacking, and UV absorption increases.

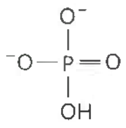
12.



Deoxyribose



Guanine



Phosphate

Solubilities: phosphate > deoxyribose > guanine. The highly polar phosphate groups and sugar moieties are on the outside of the double helix, exposed to water; the hydrophobic bases are in the interior of the helix.

13. Primer 1: CCTCGAGTCAATCGATGCTG

Primer 2: CGCGCACATCAGACGAACCA

Recall that all DNA sequences are written in the 5′→3′ direction, left to right; that DNA polymerase synthesizes DNA in the 5′→3′ direction; that the two strands of a DNA molecule are antiparallel; and that both PCR primers must target the end sequences so that their 3′ ends are oriented toward the segment to be amplified.

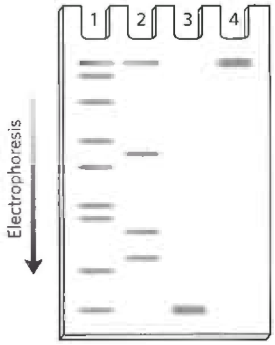
14. (a) B **(b)** C **(c)** A

15. The primers can be used to probe libraries containing long genomic clones to identify contig ends that lie close to each other. If the contigs flanking the gap are close enough, the primers can be used in PCR to directly amplify the intervening DNA separating the contigs, which can then be cloned and sequenced.

16. The 3′-H would prevent addition of any subsequent nucleotides, so the sequence for each cluster would end after the first nucleotide addition.

17. If dCTP is omitted, when the first G residue is encountered in the template, ddCTP will be added, and polymerization will halt. Only one band will be seen in the sequencing gel.

18.



19. The products are:

(5′)GCGCCAUUGC(3′)—OH

(5′)GCGCCAUUG(3′)—OH

(5′)GCGCCAUU(3′)—OH

(5′)GCGCCAU(3′)—OH

(5′)GCGCCA(3′)—OH

(5′)GCGCC(3′)—OH

(5′)GCGC(3′)—OH

(5′)GCG(3′)—OH

(5′)GC(3′)—OH

and the nucleoside 5′-phosphates

20. (a) Water is a participant in most biological reactions, including those that cause mutations. The low water content in endospores reduces the activity of mutation-causing enzymes and slows the rate of nonenzymatic depurination reactions, which are hydrolysis reactions. **(b)** UV light induces formation of cyclobutane pyrimidine dimers. Because *B. subtilis* is a soil organism, spores can be lofted to the top of the soil or into the air, where they may be subject to prolonged UV exposure.

21. DMT is a blocking group that prevents reaction of the incoming base with itself.

22. (a) Right-handed. The base at one 5′ end is adenine; at the other 5′ end, cytosine. **(b)** Left-handed **(c)** If you cannot see the structures in stereo, use a search engine to find tips online.

23. (a) It would not be easy! The data for different samples from the same organism show significant variation, and the recovery is never 100%. The numbers for C and T show much more consistency than those for A and G, so for C and T it is much easier to make the case that samples from the same organism have the same composition. But even with the less consistent values for A and G, (1) the range of values for different tissues does overlap substantially; (2) the difference between different preparations of the same tissue is about the same as the difference between samples from different tissues; and (3) in samples for which recovery is high, the numbers are more consistent. **(b)** This technique would not be sensitive enough to detect a difference between normal cells and cancerous cells. Cancer is caused by mutations, but these changes in DNA—a few base pairs out of several billion—would be too small to detect with these techniques. **(c)** The ratios of A:G and T:C vary widely among different species. For example, in the bacterium *Serratia marcescens*, both ratios are 0.4, meaning that the DNA contains mostly G and C. In *Haemophilus influenzae*, by contrast, the ratios are 1.74 and 1.54, meaning that the DNA is mostly A and T. **(d)** Conclusion 4 has three requirements. (1) A = T: The table shows an A:T ratio very close to 1 in all cases. Certainly, the variation in this ratio is substantially less than the variation in the A:G and T:C ratios. (2) G = C: Again, the G:C ratio is very close to 1, and the other ratios vary widely. (3) A + G = T + C: This is the purine:pyrimidine ratio, which also is very close to 1.

Chapter 9

1. (a) (5′) – – – G(3′) and (5′)AATTC – – – (3′)
(3′) – – – CTTAA(5′) (3′) G – – – (5′)

(g) (5′) – – – CAGAATTC – – – (3′)
(3′) – – – GTCTTAAG – – – (5′)

(h) Method 1: Cut the DNA with EcoRI as in (a), then treat the DNA as in (b) or (d), and then ligate a synthetic DNA fragment with the BamHI recognition sequence between the two resulting blunt ends. Method 2 (more efficient): Synthesize a DNA fragment with the structure

(5′)AATTGGATCC(3′)
(3′)CCTAGGTTAA(5′)

This would ligate efficiently to the sticky ends generated by EcoRI cleavage, would introduce a BamHI site, but would not regenerate the EcoRI site.

(i) The four fragments (with N = any nucleotide), in order of discussion in the problem, are

(5′)AATTCNNNNCTGCA(3′)
(3′)GNNNNG(5′)

(5′)AATTCNNNNGTGCA(3′)
(3′)GNNNNC(5′)

(5′)AATTGNNNNCTGCA(3′)
(3′)CNNNNG(5′)

(5′)AATTGNNNNGTGCA(3′)
(3′)CNNNNC(5′)

2. Yeast artificial chromosomes (YACs) are not stable in a cell unless they have two telomere-containing ends and a large DNA segment cloned into the chromosome. YACs less than 10,000 bp long are soon lost during continued mitosis and cell division.

3. (a) Plasmids in which the original pBR322 was regenerated without insertion of a foreign DNA fragment; these would retain resistance to ampicillin. Also, two or more molecules of pBR322 might be ligated together with or without insertion of foreign DNA.

(b) The clones in lanes 1 and 2 each have one DNA fragment inserted in different orientations. The clone in lane 3 has two DNA fragments, ligated such that the EcoRI proximal ends are joined.

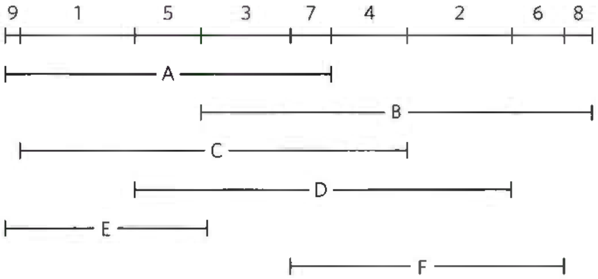
4. (5′)GAAAGTCCGCGTTATAGGCATG(3′)
(3′)ACGTCTTTCAGGCGCAATATCCGTACTTAA(5′)

5. Your test would require DNA primers, a heat-stable DNA polymerase, deoxynucleoside triphosphates, and a PCR machine (thermal cycler). The primers would be designed to amplify a DNA segment encompassing the CAG repeat. The DNA strand shown is the coding strand, oriented 5′→3′, left to right. The primer targeted to DNA to the left of the repeat would be identical to any 25-nucleotide sequence shown in the region to the left of the CAG repeat. The primer on the right side must be complementary and antiparallel to a 25-nucleotide sequence to the right of the CAG repeat. Using the primers, DNA including the CAG repeat would be amplified by PCR, and its size would be determined by comparison with size markers after electrophoresis. The length of the DNA would reflect the length of the CAG repeat, providing a simple test for the disease.

6. Design PCR primers that are complementary to the DNA in the deleted segment but would direct DNA synthesis away from each other. No PCR product is generated unless the ends of the deleted segment are joined to create a circle.

7. The two proteins likely co-localize under nutrient starvation and possibly form a protein complex.

8.



9. The production of labeled antibodies is difficult and expensive, and the labeling of every antibody to every protein target would be impractical. By labeling one antibody preparation for binding to all antibodies of a particular class, the same labeled antibody preparation can be used in many different immunofluorescence experiments.

10. Express the protein in yeast strain 1 as a fusion protein with one of the domains of Gal4p—say, the DNA-binding domain. Using yeast strain 2, make a library in which essentially every protein of the fungus is expressed as a fusion protein with the interaction domain of Gal4p. Mate strain 1 with the strain 2 library, and look for colonies that are colored due to expression of the reporter gene. These colonies will generally arise from mated cells containing a fusion protein that interacts with your target protein.

11. Reverse transcriptase is used to convert single-stranded RNA into double-stranded DNA in one of the early steps of RNA-Seq.

12. RNA-Seq detects noncoding RNAs. These have special functions, and they lack protein-coding sequences. Many RNAs encoded by eukaryotic genomes are not messenger RNAs. Instead, they are noncoding RNAs with a variety of functions. They need not possess an open reading frame as part of their sequence.

13. ATSAAG**W**DEWEGGK**V**LIHL**DG**KLQNRGALLELDIGAV

14. The pattern of haplotypes in the Aleut and Eskimo populations suggests that their ancestors' migration into the American Arctic regions was separate from the migrations that eventually populated the rest of North America and South America.

15. Interbreeding between the Denisovans and *Homo sapiens* must have occurred in Asia, sometime in the many millennia during which humans migrated from Africa to Asia and then to Australia and Melanesia.

16. The same disease condition can be caused by defects in two or more genes that are on different chromosomes.

17. (b) would act as a suitable primer pair for this transcript; **(a)** would form primer dimers because of the high number of complementary bases in the primers; **(c)** also exhibits significant self-complementarity and would have a very high melting point due to the C–G pairs; **(d)** also exhibits self-complementarity and would form stem-loops.

18. (a) DNA solutions are highly viscous because the very long molecules are tangled in solution. Shorter molecules tend to tangle less and form a less viscous solution, so decreased viscosity corresponds to shortening of the polymers—as caused by nuclease activity. **(b)** An endonuclease. An exonuclease removes single nucleotides from the 5′ end or 3′ end and would produce TCA-soluble ^{32}P-labeled nucleotides. An endonuclease cuts DNA into oligonucleotide fragments and produces little or no TCA-soluble ^{32}P-labeled material. **(c)** The 5′ end. If the phosphate were left on the 3′ end, the kinase would incorporate significant ^{32}P as it added phosphate to the 5′ end; treatment with the phosphatase would have no effect on this. In this case, samples A and B would incorporate significant amounts of ^{32}P. When the phosphate is left on the 5′ end, the kinase does not incorporate any ^{32}P: it cannot add a phosphate if one is already present. Treatment with the phosphatase removes 5′ phosphate, and the kinase then incorporates significant amounts of ^{32}P. Sample A will have little or no ^{32}P, and B will show substantial ^{32}P incorporation—as was observed. **(d)** Random breaks would produce a distribution of fragments of random size. The production of specific fragments indicates that the enzyme is site-specific. **(e)** Cleavage at the site of recognition. This produces a specific sequence at the 5′ end of the fragments. If cleavage occurred near but not within the recognition site, the sequence at the 5′ end of the fragments would be random. **(f)** The results are consistent with two recognition sequences, as shown below, cleaved where shown by the arrows:

↓
(5′) – – – GTT AAC – – – (3′)
(3′) – – – CAA TTG – – – (5′)
↑

which gives the (5′)pApApC and (3′)TpTp fragments; and

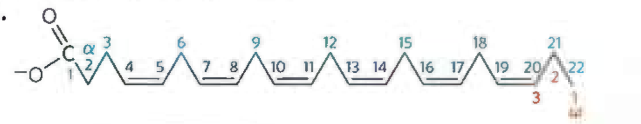
↓
(5′) – – – GTC GAC – – – (3′)
(3′) – – – CAG CTG – – – (5′)
↑

which gives the (5′)pGpApC and (3′)CpTp fragments.

Chapter 10

1. The term "lipid" does not specify a particular chemical structure. Compounds are categorized as lipids based on their greater solubility in organic solvents than in water.

2.



20:6($\Delta^{4,7,10,13,16,19}$) Docosahexaenoic acid (DHA)

3. (a) The number of cis double bonds. Each cis double bond causes a bend in the hydrocarbon chain, lowering the melting temperature. **(b)** Six different triacylglycerols can be constructed, in order of increasing melting points:

OOO < OOP = OPO < PPO = POP < PPP

(c) where O = oleic and P = palmitic acid. The greater the content of saturated fatty acid, the higher the melting point. **(d)** Branched-chain fatty acids increase the fluidity of membranes because they decrease the extent of membrane lipid packing.

4. It reduces double bonds, which increases the melting point of lipids containing the fatty acids.

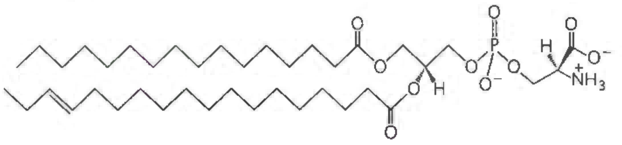
5. Long, saturated acyl chains, nearly solid at air temperatures, form a hydrophobic layer in which a polar compound such as H_2O cannot dissolve or diffuse.

6. Spearmint is (*R*)-carvone; caraway is (*S*)-carvone.

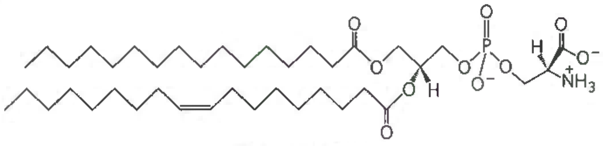
7. The ^{18}O label appears in the fatty acid salts.

8. *Hydrophobic units:* **(a)** 2 fatty acids **(b)**, **(c)**, and **(d)** 1 fatty acid and the hydrocarbon chain of sphingosine **(e)** the steroid nucleus and acyl side chain. *Hydrophilic units:* **(a)** phosphoethanolamine **(b)** phosphocholine **(c)** D-galactose **(d)** several sugar molecules **(e)** alcohol group (—OH)

9. Serine



10.



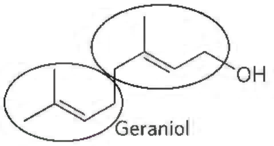
Phosphatidylserine

11. The part of the membrane lipid that determines blood type is the oligosaccharide in the head group of the membrane sphingolipids (see Fig. 10-13). This same oligosaccharide is attached to certain membrane glycoproteins, which also serve as points of recognition by the antibodies that distinguish blood groups.

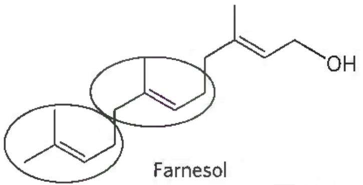
12. (a) The free —OH group on C-2 and the phosphocholine head group on C-3 are hydrophilic; the fatty acid on C-1 of lysolecithin is hydrophobic. **(b)** Certain steroids, such as prednisone, inhibit the action of phospholipase A_2, inhibiting the release of arachidonic acid from C-2. Arachidonic acid is converted to a variety of eicosanoids, some of which cause inflammation and pain. **(c)** Phospholipase A_2 releases arachidonic acid, a precursor of other eicosanoids with vital protective functions in the body; it also breaks down dietary glycerophospholipids.

13. Diacylglycerol is hydrophobic and remains in the membrane. Inositol 1,4,5-trisphosphate is highly polar, very soluble in water, and more readily diffusible in the cytosol. Both are second messengers.

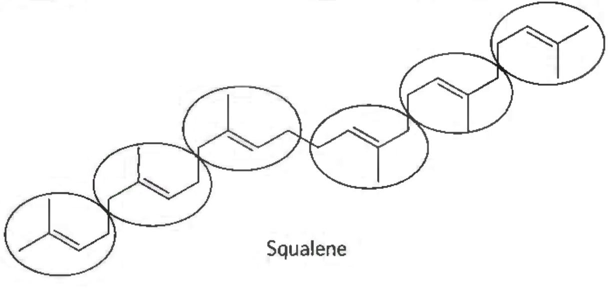
14.



Geraniol



Farnesol



Squalene

15. (a) Glycerol and the sodium salts of palmitic and stearic acids **(b)** D-Glycerol 3-phosphocholine and the sodium salts of palmitic and oleic acids

16. Solubility in water: monoacylglycerol > diacylglycerol > triacylglycerol

17. First eluted to last eluted: cholesteryl palmitate and triacylglycerol; cholesterol and *n*-tetradecanol; phosphatidylcholine and phosphatidylethanolamine; sphingomyelin; phosphatidylserine and palmitate. The lipids elute from the silica gel column in order of polarity. The least polar lipid will elute first and the most polar lipid will elute last.

18. (a) Subject acid hydrolysates of each compound to chromatography (GC or silica gel TLC), and compare the result with known standards. *Sphingomyelin hydrolysate:* sphingosine, fatty acids, phosphocholine, choline, and phosphate; *cerebroside hydrolysate:* sphingosine, fatty acids, sugars, but no phosphate. **(b)** Strong alkaline hydrolysis of sphingomyelin yields sphingosine; phosphatidylcholine yields glycerol. Detect hydrolysate components on thin-layer chromatograms by comparing with standards or by their differential reaction with FDNB (only sphingosine reacts to form a colored product). Treatment with phospholipase A_1 or A_2 releases free fatty acids from phosphatidylcholine, but not from sphingomyelin.

19. (a) Sphingosine (4.78); linoleic acid (5.88); stearic acid (6.33); cholesterol (7.68) **(b)** Log *P* describes the lipophilicity of the drug, crucial for determining how to formulate the drug for transport through aqueous compartments of the body such as the gut and the bloodstream. Log *P* also determines the likelihood of a drug being absorbed by fats and fatty tissues, which can alter its effectiveness, half-life, and potential toxicity.

20. (a) β barrel **(b)** Phe, Trp, Tyr, Leu. All are hydrophobic or have nonpolar R groups. **(c)** The polar head group can hydrogen bond with water; the hydrocarbon tail cannot. Hydrophobic portions of the residues of the pocket protect the tail from contact with water as it moves through the bloodstream.

21. (a) GM1 and globoside. Both glucose and galactose are hexoses, so "hexose" in the molar ratio refers to glucose + galactose. The ratios for the four gangliosides are GM1, 1:3:1:1; GM2, 1:2:1:1; GM3, 1:2:0:1; globoside, 1:3:1:0. **(b)** Yes. The ratio matches GM2, the ganglioside expected to build up in Tay-Sachs disease (see Box 10-1, Fig. 1). **(c)** This analysis is similar to that used by Sanger to determine the amino acid sequence of insulin. The analysis of each fragment reveals only its *composition*, not its *sequence*, but because each fragment is formed by sequential removal of one sugar, we can draw conclusions about sequence. The structure of the normal asialoganglioside is ceramide–glucose–galactose–galactosamine–galactose, consistent with Box 10-1 (excluding Neu5Ac, removed before hydrolysis). **(d)** The Tay-Sachs asialoganglioside is ceramide–glucose–galactose–galactosamine, consistent with Box 10-1. **(e)** The structure of the normal asialoganglioside, GM1, is *ceramide–glucose* [2 —OH involved in glycosidic links; 1 —OH involved in ring structure; 3 —OH (2, 3, 6) free for methylation]–*galactose* [2 —OH in links; 1 —OH in ring; 3 —OH (2, 4, 6) free for methylation]–*galactosamine* [2 —OH in links; 1 —OH in ring; 1 —NH_2 instead of —OH; 2 —OH (4, 6) free for methylation]–*galactose* [1 —OH in link; 1 —OH in ring; 4 —OH (2, 3, 4, 6) free for methylation]. **(f)** Two key pieces of information are missing: What are the linkages between the sugars? Where is Neu5Ac attached?

Chapter 11

1. The area per molecule would be calculated from the known amount (number of molecules) of lipid used and the area occupied by a monolayer when it begins to resist compression (when the required force increases dramatically, as shown in the plot of force versus area).

2. (a) Lipids that form bilayers are amphipathic molecules: they contain a hydrophilic region and a hydrophobic region. To minimize the hydrophobic area exposed to the water surface, these lipids form two-dimensional sheets, with the hydrophilic regions exposed to water and the hydrophobic regions buried in the interior of the sheet. Furthermore, to avoid exposing the hydrophobic edges of the sheet to water, lipid bilayers close on themselves. **(b)** These sheets form the closed membrane surfaces that envelop cells and compartments within cells (organelles).

3. 2 nm. Two palmitates placed end to end span about 4 nm, approximately the thickness of a typical bilayer.

4. Integral proteins are firmly embedded in the lipid bilayer and can be released only by treating membranes with a detergent or nonpolar solvent. Peripheral membrane proteins are more easily released, by changes in pH, metal ion concentration, or protein-denaturing reagents like urea. Amphitropic membrane proteins are loosely and reversibly associated with membranes and move between membrane and cytosol as part of their function.

5. Salt extraction indicates a peripheral location, and inaccessibility to protease in intact cells indicates an internal location. Protein X is likely to be a peripheral protein on the cytosolic face of the membrane.

6. Construct a hydropathy plot; hydrophobic regions of 20 or more residues suggest transmembrane segments. Determine whether the protein in intact erythrocytes reacts with a membrane-impermeant reagent specific for primary amines; if it does, the transporter's amino terminus is on the outside of the cell.

7. ~4%; estimated by calculating the surface area of the cell and of 10,000 transporter molecules

8. ~22. To estimate the fraction of membrane surface covered by phospholipids, you would need to know (or estimate) the average cross-sectional area of a phospholipid molecule in a bilayer (e.g., from an experiment such as that described in Problem 1 in this chapter) and the average cross-sectional area of a 50 kDa protein.

9. Rate of diffusion would decrease. Movement of individual lipids in bilayers occurs much faster at 37 °C, when the lipids are in the "fluid" phase, than at 10 °C, when they are in the "solid" phase. This effect is more pronounced than the usual decrease in Brownian motion with decreased temperature.

10. Interactions among membrane lipids are due to the hydrophobic effect, noncovalent and reversible, allowing membranes to spontaneously reseal.

11. The temperature of body tissues at the extremities is lower than that of tissues closer to the center of the body. If lipid is to remain fluid at this lower temperature, it must contain a higher proportion of unsaturated fatty acids; unsaturated fatty acids lower the melting point of lipid mixtures.

12. There is a very high energetic barrier to taking the polar head of a membrane lipid through the hydrocarbon core. Higher temperatures might make it more likely to occur, as would the presence of a catalyst, such as a flippase, a floppase, or a scramblase protein.

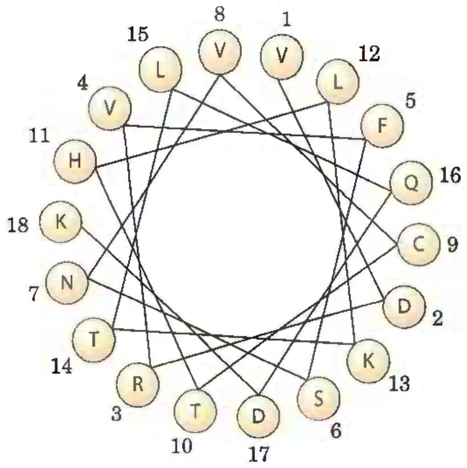
13. The energetic cost of moving the highly polar, sometimes charged, head group through the hydrophobic interior of the bilayer is prohibitive.

14. Scramblases catalyze the transport of membrane lipids from one membrane leaflet to the other. The reaction is ATP-independent, driven by a transbilayer lipid gradient. Scramblases cannot create an asymmetric distribution of lipids across the bilayer. Flippases catalyze the ATP-dependent transport of aminophospholipids (phosphatidylserine and phosphatidylethanolamine) from the extracellular or lumenal leaflet of a membrane to the cytosolic leaflet.

15. At pH 7, tryptophan bears both a positive charge and a negative charge, but indole is uncharged. The movement of the less polar indole through the hydrophobic core of the bilayer is energetically more favorable.

16. The transporter has a K_t greater than 0.2 mM and it is a cotransporter, a symporter with Na^+.

17.



The amino acids with the greatest hydropathy index (V, L, F, and C) are clustered on one side of the helix. This amphipathic helix is likely to dip into the lipid bilayer along its hydrophobic surface while exposing its other surface to the aqueous phase. Alternatively, a group of helices may cluster with their polar surfaces in contact with one another and their hydrophobic surfaces facing the lipid bilayer.

18. 0.60 mol

19. Valinomycin is an ionophore that will carry K^+ across the plasma membrane, deflating the membrane potential that is normally achieved by the unequal pumping of Na^+ and K^+ by the Na^+K^+ ATPase.

20. 13 kJ/mol

21. Most of the O_2 consumed by a tissue is for oxidative phosphorylation, the source of most of the ATP. Therefore, about two-thirds of the ATP synthesized by the kidney is used for pumping K^+ and Na^+.

22. Under normal conditions, the Na^+Ca^{2+} exchanger pumps Ca^{2+} out as it allows Na^+ to move inward. The excess of Na^+ on the outside is created by the Na^+K^+ ATPase. When that enzyme is blocked with digoxin, the Na^+ gradient is depleted, and with it, the driving force for Ca^{2+} exit. So Ca^{2+} would flow down its gradient, entering the cell. This (increased Ca^{2+} concentration) is generally lethal for the cell.

23. No. The symporter may carry more than one equivalent of Na^+ for each mole of glucose transported.

24. Treat a suspension of cells with unlabeled NEM in the presence of excess lactose, remove the lactose, then add radiolabeled NEM. Use SDS-polyacrylamide gel electrophoresis (SDS-PAGE) to determine the M_r of the radiolabeled band (the transporter).

25. ATP-dependence signifies active transport; $[Na^+]$-independence suggests primary transport.

26. The leucine transporter is specific for the L isomer, but the binding site can accommodate either L-leucine or L-valine. Reduction of V_{max} in the absence of Na^+ indicates that leucine (or valine) is transported by symport with Na^+. By depleting the Na^+ gradient, ouabain would inhibit L-leucine uptake.

27. The K^+ channel has a "pore" that allows K^+ to diffuse through the channel, stabilized by its interaction with the carbonyl oxygens of the amino acids that line the pore. Na^+ is smaller than K^+, so it is not sterically hindered from passage through the pore, but Na^+ is *too small* to interact with the carbonyl oxygens, so it is not stabilized by that interaction.

28. V_{max} increases; K_t is unaffected.

29. **(a)** Glycophorin A: 1 transmembrane segment; myoglobin: no segments long enough to cross a membrane (not a membrane protein); aquaporin: 6 transmembrane segments (may be a membrane channel or a receptor protein) **(b)** The 15 residue window provides a better signal-to-noise ratio. **(c)** A narrower window reduces the impact of "edge effects" when a transmembrane sequence occurs near either end of the protein.

30. **(a)** The rise per residue for an α helix (Chapter 4) is about 1.5 Å = 0.15 nm. To span a 4 nm bilayer, an α helix must contain about 27 residues; thus, for seven spans, about 190 residues are required. A protein of M_r 64,000 has about 580 residues. **(b)** A hydropathy plot is used to locate transmembrane regions. **(c)** Because about half of this portion of the receptor consists of charged residues, it probably represents an intracellular loop that connects two adjacent membrane-spanning regions of the protein. **(d)** Because this helix is composed mostly of hydrophobic residues, this portion of the receptor is probably one of the membrane-spanning regions of the protein.

31. **(a)** *Model A:* supported. The two dark lines are either the protein layers or the phospholipid heads, and the clear space is either the bilayer or the hydrophobic core, respectively. *Model B:* not supported. This model requires a more-or-less uniformly stained band surrounding the cell. *Model C:* supported, with one reservation. The two dark lines are the phospholipid heads; the clear zone is the tails. This assumes that the membrane proteins are not visible, because they do not stain with osmium or do not happen to be in the sections viewed. **(b)** *Model A:* supported. A "naked" bilayer (4.5 nm) + two layers of protein (2 nm) sums to 6.5 nm, which is within the observed range of thickness. *Model B:* neither. This model makes no predictions about membrane thickness. *Model C:* unclear. The result is hard to reconcile with this model, which predicts a membrane as thick as, or slightly thicker than (due to the projecting ends of embedded proteins), a "naked" bilayer. The model is supported only if the smallest values for membrane thickness are correct or if a substantial amount of protein projects from the bilayer. **(c)** *Model A:* unclear. The result is hard to reconcile with this model. If the proteins are bound to the membrane by ionic interactions, the model predicts that the proteins contain a high proportion of charged amino acids, in contrast to what was observed. Also, because the protein layer must be very thin (see (b)), there would not be much room for a hydrophobic protein core, so hydrophobic residues would be exposed to the solvent. *Model B:* supported. The proteins have a mixture of hydrophobic residues (interacting with lipids) and charged residues (interacting with water). *Model C:* supported. The proteins have a mixture of hydrophobic residues (anchoring in the membrane) and charged residues (interacting with water). **(d)** *Model A:* unclear. The result is hard to reconcile with this model, which predicts a ratio of exactly 2.0; this would be hard to achieve under physiologically relevant pressures. *Model B:* neither. This model makes no predictions about amount of lipid in the membrane. *Model C:* supported. Some membrane surface area is taken up with proteins, so the ratio would be less than 2.0, as was observed under more physiologically relevant conditions. **(e)** *Model A:* unclear. The model predicts proteins in extended conformations rather than globular conformations, so is supported only if one assumes that proteins layered on the surfaces include helical segments. *Model B:* supported. The model predicts mostly globular proteins (containing some helical segments). *Model C:* supported. The model predicts mostly globular proteins. **(f)** *Model A:* unclear. The phosphorylamine head groups are protected by the protein layer, but only if the proteins completely cover the surface will the phospholipids be completely protected from phospholipase. *Model B:* supported. Most head groups are accessible to phospholipase. *Model C:* supported. All head groups are accessible to phospholipase. **(g)** *Model A:* not supported. Proteins are entirely accessible to trypsin digestion, and virtually all will undergo multiple cleavage, with no protected hydrophobic segments. *Model B:* not supported. Virtually all proteins are in the bilayer and inaccessible to trypsin. *Model C:* supported. Segments of protein that penetrate or span the bilayer are protected from trypsin; those exposed at the surfaces will be cleaved. The trypsin-resistant portions have a high proportion of hydrophobic residues.

Chapter 12

1. X is cAMP; its production is stimulated by epinephrine. **(a)** Centrifugation sediments adenylyl cyclase (which catalyzes cAMP formation) in the particulate fraction. **(b)** Added cAMP stimulates glycogen phosphorylase. **(c)** cAMP is heat-stable; it can be prepared by treating ATP with barium hydroxide.

2. Unlike cAMP, dibutyryl cAMP passes readily through the plasma membrane.

3. (a) It increases [cAMP]. **(b)** cAMP regulates Na^+ permeability. **(c)** Replace lost body fluids and electrolytes.

4. (a) The mutation makes R unable to bind and inhibit C, so C is constantly active. **(b)** The mutation prevents cAMP binding to R, leaving C inhibited by bound R.

5. Albuterol raises [cAMP], leading to relaxation and dilation of the bronchi and bronchioles. Because β-adrenergic receptors control many other processes, this drug would have undesirable side effects. To minimize these effects, find an agonist specific for the subtype of β-adrenergic receptors found in bronchial smooth muscle.

6. Hormone degradation; hydrolysis of GTP bound to a G protein; degradation, metabolism, or sequestration of second messenger; receptor desensitization; removal of receptor from the cell surface.

7. Fuse CFP to β-arrestin and fuse YFP to the cytoplasmic domain of the β-adrenergic receptor, or vice versa. In either case, illuminate at 433 nm and observe fluorescence at both 476 nm and 527 nm. If the interaction occurs, emitted light intensity will decrease at 476 nm and increase at 527 nm upon addition of epinephrine to cells expressing the fusion proteins. If the interaction does not occur, the wavelength of emitted light will remain at 476 nm. Some reasons why this might fail: the fusion proteins (1) are inactive or otherwise unable to interact, (2) are not translocated to their normal subcellular location, or (3) are not stable to proteolytic breakdown.

8. Vasopressin acts by elevating cytosolic $[Ca^{2+}]$ to 10^{-6} M, activating protein kinase C. EGTA injection blocks vasopressin action but should not affect the response to glucagon, which uses cAMP, *not* Ca^{2+}, as second messenger.

9. Amplify: (a), (b), (e), (f). Terminate: (c), (d), (f). (f) can contribute to both.

10. IRS1, Grb2, Sos, Ras, Raf, MEK, ERK

11. A mutation in *ras* that inactivated the Ras GTPase activity would create a protein that, once activated by the binding of GTP, would continue to give, through Raf, the insulin-response signal.

12. *Shared properties of Ras and G_s:* Both bind either GDP or GTP; both are activated by GTP; both, when active, activate a downstream enzyme; both have intrinsic GTPase activity that shuts them off after a short period of activation. *Differences:* Ras is a small, monomeric protein; G_s is heterotrimeric. *Functional difference between G_s and G_i:* G_s activates adenylyl cyclase; G_i inhibits it.

13. *Kinase (factor in parentheses):* PKA (cAMP); PKG (cGMP); PKC (Ca^{2+}, DAG); Ca^{2+}/CaM kinase (Ca^{2+}, CaM); cyclin-dependent kinase (cyclin); receptor Tyr kinase (ligand for the receptor, such as insulin); MAPK (Raf); Raf (Ras); glycogen phosphorylase kinase (PKA).

14. G_s remains in its activated form when the nonhydrolyzable analog is bound. The analog therefore prolongs the effect of epinephrine on the injected cell.

15. Individuals with Oguchi disease might have a defect in rhodopsin kinase or in arrestin.

16. Rod cells would no longer show any change in membrane potential in response to light. This experiment has been done. Illumination did activate PDE, but the enzyme could not significantly reduce the 8-Br-cGMP level, which remained well above that needed to keep the gated ion channels open. Thus, light had no impact on membrane potential.

17. Insulin increases glycogen synthesis.

18. Nearly every component of the β-adrenergic and insulin receptor signaling pathways communicates signal activation by some connection through an IDR. The activation loop of protein kinases is an IDR, and the carboxyl-terminal end of most of the protein kinases in those pathways is an IDR. AKAPs and other scaffold proteins serve as anchors to hold pathway components in proximity. Phosphorylation/dephosphorylation of IDRs serves as a switch for the ability of the target proteins to associate.

19. (b), (c), (e), (d), (a)

20. (a) On exposure to heat, TRPV1 channels open, causing an influx of Na^+ and Ca^{2+} into the sensory neuron. This depolarizes the neuron, triggering an action potential. When the action potential reaches the axon terminus, neurotransmitter is released, signaling to the nervous system that heat has been sensed. **(b)** Capsaicin mimics the effects of heat by opening TRPV1 at low temperatures, leading to the false sensation of heat. The extremely low EC_{50} indicates that even very small amounts of capsaicin will have dramatic sensory effects. **(c)** At low levels, menthol should open the TRPM8 channel, leading to a sensation of cool; at high levels, both TRPM8 and TRPV3 open, leading to a mixed sensation of cool and heat, such as you may have experienced with very strong peppermints.

21. (a) These mutations might lead to permanent activation of the PGE_2 receptor, leading to unregulated cell division and tumor formation. **(b)** The viral gene might encode a constitutively active form of the receptor, causing a constant signal for cell division and thus tumor formation. **(c)** E1A protein might bind to pRb and prevent E2F from binding, so E2F is constantly active and cells divide uncontrollably. **(d)** Lung cells do not normally respond to PGE_2 because they do not express the PGE_2 receptor; mutations resulting in a constitutively active PGE_2 receptor would not affect lung cells.

22. A normal tumor suppressor gene encodes a protein that restrains cell division. A mutant form of the protein fails to suppress cell division, but if either of the two alleles in an individual encodes a normal protein, normal function will continue. A normal oncogene encodes a regulator protein that triggers cell division, but only when an appropriate signal (growth factor) is present. The mutant version of the oncogene product constantly sends the signal to divide, whether or not growth factors are present.

23. In a child who develops multiple tumors in both eyes, every retinal cell had a defective copy of the *Rb* gene at birth. Early in the child's life, several cells independently underwent a second mutation that damaged the one good *Rb* allele, producing a tumor. A child who develops a single tumor had, at birth, two good copies of the *Rb* gene in every cell; mutation in both *Rb* alleles in one cell (extremely rare) caused the single tumor.

24. Two cells expressing the same surface receptor may have access to different complements of target proteins for protein phosphorylation and therefore have different responses to the same signal.

25. (a) The data favor the cell-based model, which predicts different receptors present on different cells. **(b)** This experiment addresses the issue of the independence of different taste sensations. Even though the receptors for sweet and/or umami are missing, the animals' other taste sensations are normal; thus, pleasant and unpleasant taste sensations are independent. **(c)** Yes. Loss of either T1R1 or T1R3 subunits abolishes umami taste sensation. **(d)** Both models. With either model, removing one receptor would abolish that taste sensation. **(e)** Yes. Loss of either the T1R2 or T1R3 subunits almost completely abolishes the sweet taste sensation; complete elimination of sweet taste requires deletion of both subunits. **(f)** At very high sucrose concentrations, T1R2 and, to a lesser extent, T1R3 receptors, as homodimers, can detect sweet taste. **(g)** The results are consistent with either model of taste encoding, but they do strengthen the researchers' conclusions. Ligand binding can be completely separated from taste sensation. If the ligand for the receptor in "sweet-tasting cells" binds a molecule, mice prefer that molecule as a sweet compound.

Chapter 13

1. Consider the developing chick as the system; the nutrients, egg shell, and outside world are the surroundings. Transformation of the single cell into a chick drastically reduces the entropy of the system. Initially, the parts of the egg outside the embryo (the surroundings) contain complex fuel molecules (a low-entropy condition). During incubation, some of these complex molecules are converted to large numbers of CO_2 and H_2O molecules (high entropy). This increase in the entropy of the surroundings is larger than the decrease in entropy of the chick (the system).

2. (a) –4.8 kJ/mol **(b)** 7.56 kJ/mol **(c)** –13.7 kJ/mol

3. (a) 262 **(b)** 608 **(c)** 0.30

4. $K'_{eq} = 21$; $\Delta G'^{\circ} = -7.6$ kJ/mol

5. –31 kJ/mol

6. (a) –1.68 kJ/mol **(b)** –4.4 kJ/mol **(c)** At a given temperature, the value of $\Delta G'^{\circ}$ for any reaction is fixed and is defined for standard conditions (here, both fructose 6-phosphate and glucose 6-phosphate at 1 M). In contrast, ΔG is a variable that can be calculated for any set of reactant and product concentrations.

7. $K'_{eq} \approx 1$; $\Delta G'^{\circ} \approx 0$

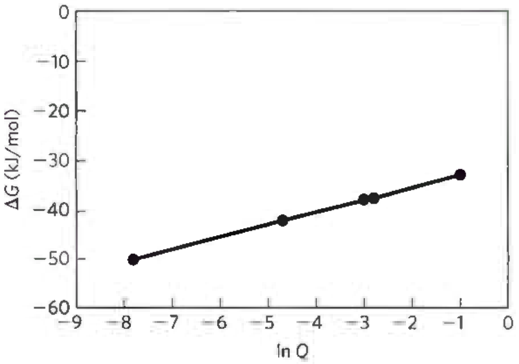
8. Less. The overall equation for ATP hydrolysis can be approximated as

$$ATP^{4-} + H_2O \rightarrow ADP^{3-} + HPO_4^{2-} + H^+$$

(This is only an approximation, because the ionized species shown here are the major, but not the only, forms present.) Under standard conditions ($[ATP] = [ADP] = [P_i] = 1$ M), the concentration of water is 55 M and does not change during the reaction. Because H^+ ions are produced in the reaction, at a higher $[H^+]$ (pH 5.0) the equilibrium would be shifted to the left and less free energy would be released.

9. 10

10.



ΔG for ATP hydrolysis is lower when [ATP]/[ADP] is low ($\ll 1$) than when [ATP]/[ADP] is high. Less energy is available to the cell from a given [ATP] when the [ATP]/[ADP] ratio falls and more is available when it rises.

11. (a) 4.74×10^{-3} M^{-1}; [glucose 6-phosphate] = 1.1×10^{-7} M. No. The cellular [glucose 6-phosphate] is much greater than this, favoring the reverse reaction. **(b)** 11 M. No. The maximum solubility of glucose is less than 1 M. **(c)** 651 ($\Delta G'^{\circ} = -16.7$ kJ/mol); [glucose] = 1.5×10^{-7} M. Yes. This reaction path can occur with a concentration of glucose that is readily soluble and does not produce a large osmotic force. **(d)** No. This would require such high $[P_i]$ that the phosphate salts of divalent cations would precipitate. **(e)** By directly transferring the phosphoryl group from ATP to glucose, the phosphoryl group transfer potential ("tendency" or "pressure") of ATP is utilized without generating high concentrations of intermediates. The essential part of this transfer is, of course, the enzymatic catalysis.

12. (a) –12.5 kJ/mol **(b)** –14.6 kJ/mol

13. (a) 3.16×10^{-4} **(b)** 68.7 **(c)** 7.39×10^{4}

14. –13 kJ/mol

15. 46.7 kJ/mol

16. Isomerization moves the carbonyl group from C-1 to C-2, setting up a carbon–carbon bond cleavage between C-3 and C-4. Without isomerization, bond cleavage would occur between C-2 and C-3, generating one two-carbon compound and one four-carbon compound.

17. The mechanism is the same as that of the alcohol dehydrogenase reaction (see Fig. 14-12).

18. The first step is the reverse of an aldol condensation (see the aldolase mechanism, Fig. 14-5); the second step is an aldol condensation (see Fig. 13-4).

19. (a) Oxidation-reduction, dehydrogenase with NAD cofactor; NADH + H^+ also produced **(b)** Isomerization, isomerase **(c)** Internal rearrangement, isomerase **(d)** Phosphoryl group transfer, kinase and ATP; ADP produced **(e)** Hydrolysis, protease or peptidase and H_2O **(f)** Oxidation-reduction, dehydrogenase with NAD cofactor; NADH + H^+ also produced **(g)** Oxidation-reduction, dehydrogenase with NAD cofactor and H_2O; NADH + H^+ also produced

20. ATP; the products of phosphoarginine hydrolysis are stabilized by resonance forms not available in the intact molecule.

21. Yes. If [ADP] and [polyphosphate] are kept high, and [ATP] is kept low, the actual free-energy change would be negative.

22. (a) 46 kJ/mol **(b)** 46 kg; 68% **(c)** ATP is synthesized as it is needed, then broken down to ADP and P_i; its concentration is maintained in a steady state.

23. The ATP system is in a dynamic steady state; [ATP] remains constant because the rate of ATP consumption equals its rate of synthesis. ATP consumption involves release of the terminal (γ) phosphoryl group; synthesis of ATP from ADP involves replacement of this group. Hence the terminal phosphoryl undergoes rapid turnover. In contrast, the central (β) phosphoryl undergoes only relatively slow turnover.

24. (a) 1.7 kJ/mol **(b)** Inorganic pyrophosphatase catalyzes the hydrolysis of pyrophosphate and drives the net reaction toward the synthesis of acetyl-CoA.

25. Although all the options are possible in principle, the production of AMP and PP_i in the reaction tells us that AMP is the activating group.

26. 36 kJ/mol

27. (d) (a) (c) (b)

28. (a) NAD^+/NADH **(b)** Pyruvate/lactate **(c)** Lactate formation **(d)** –26.1 kJ/mol **(e)** 3.63×10^{4}

29. (a) Initially, electrons will be given up by lactate (converting it to pyruvate) and will flow to fumarate, converting it to succinate. **(b)** –42 kJ/mol **(c)** The four reactants have reached their equilibrium concentrations; $\Delta G = 0$.

30. (a) 1.14 V **(b)** –220 kJ/mol **(c)** ~4

31. (a) –0.35 V **(b)** –0.320 V **(c)** –0.29 V

32. In order of increasing tendency: (a), (d), (b), (c)

33. (c) and (d)

34. (a) 0.0293 **(b)** 308 **(c)** Q is much lower than K'_{eq}, indicating that the PFK-1 reaction is far from equilibrium in cells; this reaction is slower than the subsequent reactions in glycolysis. Flux through the glycolytic pathway is largely determined by the activity of PFK-1.

35. (a) 1.4×10^{-9} M **(b)** The physiological concentration (0.023 mM) is 16,000 times the equilibrium concentration; this reaction does not reach equilibrium in the cell. Many reactions in the cell are not at equilibrium.

36. Malate synthase is saturated with the substrate acetyl-CoA; its concentration is almost 10^2 greater than K_m for acetyl-CoA. But we are not given the concentration or K_m of its other substrate (glyoxylate). If [glyoxylate] is below the K_m for glyoxylate, the reaction rate is limited by [glyoxylate], and malate synthase is not operating at V_{max}.

37. (a) The lowest-energy, highest-entropy state occurs when the dye concentration is the same in both cells. If a "fish trap" gap junction allowed unidirectional transport, more of the dye would end up in the oligodendrocyte and less in the astrocyte. This would be a higher-energy, lower-entropy state than the starting state, violating the second law of thermodynamics. The model proposed by Robinson et al. requires an impossible spontaneous change from a lower-energy state to a higher-energy state without an energy input—again, thermodynamically impossible. **(b)** Molecules, unlike fish, do not exhibit *directed behavior*; they move randomly by Brownian motion. Diffusion results in *net* movement of molecules from a region of higher concentration to a region of lower concentration simply because it is more likely that a molecule on the high-concentration side will enter the connecting channel. The narrower end, like the rate-limiting step of a metabolic pathway, limits the rate at which molecules pass through; random motion of the molecules is less likely to move them through the smaller cross section. The wide end of the channel does *not* act like a funnel for molecules because the narrow end limits the rate of movement equally in both directions. When the concentrations on both sides are equal, the rates of movement in both directions are equal and there will be no change in concentration. **(c)** Fish exhibit *nonrandom behavior*. Fish behavior favors forward movement and avoids crowding and narrow places. Fish that enter the large opening of the channel tend to move forward but then are unlikely to enter the small opening because of their preferred behavior. **(d)** Here are two of many possible explanations: (1) *The dye could bind to a molecule in the oligodendrocyte.* Binding effectively removes the dye from the bulk solvent, yet it remains visible in the fluorescence microscope. (2) *The dye could be sequestered in a subcellular organelle of the oligodendrocyte*, either actively pumped in at the expense of ATP or drawn in by its attraction to other molecules in that organelle.

Chapter 14

1. At equilibrium,

$K_{eq} = 7.8 \times 10^2$ = [ADP][glucose 6-phosphate]/[ATP][glucose]

In living cells, [ADP][glucose 6-phosphate]/[ATP][glucose] = (0.5 mM)(1 mM)/(5 mM)(2 mM) = 0.05. The reaction is therefore *far* from equilibrium: the cellular concentrations of the products (glucose 6-phosphate and ADP) are much lower than expected at equilibrium, and those of the reactants are much higher. The reaction therefore tends strongly to go to the right.

2. Net equation: Glucose + 2ATP → 2 glyceraldehyde 3-phosphate + 2ADP; $\Delta G'^\circ = 2.1$ kJ/mol

3. Net equation: 2 Glyceraldehyde 3-phosphate + 4ADP + 2P_i → 2 lactate + 4ATP + 2H_2O; $\Delta G'^\circ = -114$ kJ/mol

4. –8.6 kJ/mol

5. C-1. This experiment demonstrates the reversibility of the aldolase reaction. The C-1 of glyceraldehyde 3-phosphate is equivalent to C-4 of fructose 1,6-bisphosphate (see Fig. 14-6). The starting glyceraldehyde 3-phosphate must have been labeled at C-1. The C-3 of dihydroxyacetone phosphate becomes labeled through the triose phosphate isomerase reaction, thus giving rise to fructose 1,6-bisphosphate labeled at C-3.

6. No. There would be no anaerobic production of ATP; aerobic ATP production would be diminished only slightly.

7. No. Lactate dehydrogenase is required to recycle NAD^+ from the NADH formed during the oxidation of glyceraldehyde 3-phosphate.

8. The transformation of glucose to lactate occurs when myocytes are low in oxygen, and it provides a means of generating ATP under O_2-deficient conditions. Because lactate can be oxidized to pyruvate, glucose is not wasted; pyruvate is oxidized by aerobic reactions when O_2 becomes plentiful. This metabolic flexibility gives the organism a greater capacity to adapt to its environment.

9. The cell rapidly removes the 1,3-bisphosphoglycerate in a favorable subsequent step, catalyzed by phosphoglycerate kinase.

10. (a) 3-Phosphoglycerate would be the product. **(b)** In the presence of arsenate, there is no net ATP synthesis under anaerobic conditions.

11. (a) Ethanol fermentation requires 2 mol of P_i per mole of glucose. **(b)** Ethanol is the reduced product formed during reoxidation of NADH to NAD^+, and CO_2 is the byproduct of the conversion of pyruvate to ethanol. Yes. Pyruvate must be converted to ethanol to produce a continuous supply of NAD^+ for the oxidation of glyceraldehyde 3-phosphate. Fructose 1,6-bisphosphate accumulates; it is formed as an intermediate in glycolysis. **(c)** Arsenate replaces P_i in the glyceraldehyde 3-phosphate dehydrogenase reaction to yield an acyl arsenate, which spontaneously hydrolyzes. This prevents formation of ATP, but 3-phosphoglycerate continues through the pathway.

12. Dietary niacin is used to synthesize NAD^+. Oxidations carried out by NAD^+ are part of cyclic processes, with NAD^+ as electron carrier (reducing agent); one molecule of NAD^+ can oxidize many thousands of molecules of glucose, and thus the dietary requirement for the precursor vitamin (niacin) is relatively small.

13. Dihydroxyacetone phosphate + NADH + H^+ → glycerol 3-phosphate + NAD^+ (catalyzed by a dehydrogenase)

14. *Galactokinase deficiency:* galactose (less toxic); *transferase deficiency:* galactose 1-phosphate (more toxic)

15. Consumption of alcohol forces competition for NAD^+ between ethanol metabolism and gluconeogenesis. The problem is compounded by strenuous exercise and lack of food, because at these times the level of blood glucose is already low.

16. (a) The rapid increase in glycolysis; the rise in pyruvate and NADH results in a rise in lactate. **(b)** Lactate is transformed to glucose via pyruvate. This is a slower process because formation of pyruvate is limited by NAD^+ availability, the lactate dehydrogenase equilibrium is in favor of lactate, and conversion of pyruvate to glucose is energy-requiring. **(c)** The equilibrium for the lactate dehydrogenase reaction is in favor of lactate formation.

17. Lactate is transformed to glucose in the liver by gluconeogenesis (see Fig. 14-16). A defect in FBPase-1 would prevent entry of lactate into the gluconeogenic pathway in hepatocytes, causing lactate to accumulate in the blood.

18. In the absence of O_2, the ATP needs are met by anaerobic glucose metabolism (fermentation to lactate). Because aerobic oxidation of glucose produces far more ATP than does fermentation, less glucose is needed to produce the same amount of ATP.

19. (a) There are two binding sites for ATP: a catalytic site and a regulatory site. Binding of ATP to a regulatory site inhibits PFK-1, by reducing V_{max} or increasing K_m for ATP at the catalytic site. **(b)** Glycolytic flux is reduced when ATP is plentiful. **(c)** The graph indicates that increased [ADP] suppresses the inhibition by ATP. Because the adenine nucleotide pool is fairly constant, consumption of ATP leads to an increase in [ADP]. The data show that the activity of PFK-1 may be regulated by the [ATP]/[ADP] ratio.

20. The phosphate group of glucose 6-phosphate is completely ionized at pH 7, giving the molecule an overall negative charge. Because membranes are generally impermeable to electrically charged molecules, glucose 6-phosphate cannot pass from the bloodstream into cells and hence cannot enter the glycolytic pathway and generate ATP. (This is why glucose, once phosphorylated, cannot escape from the cell.)

21. $CH_3CHO + NADH + H^+ \rightleftharpoons CH_3CH_2OH + NAD^+ \quad K'_{eq} = 1.45 \times 10^4$

22. (a) $^{14}CH_3CH_2OH$ **(b)** [3-^{14}C]glucose or [4-^{14}C]glucose

When aldolase splits glucose into two trioses phosphates, C-3 and C-4 of glucose become C-1 of the glyceraldehyde 3-phosphate that proceeds through glycolysis.

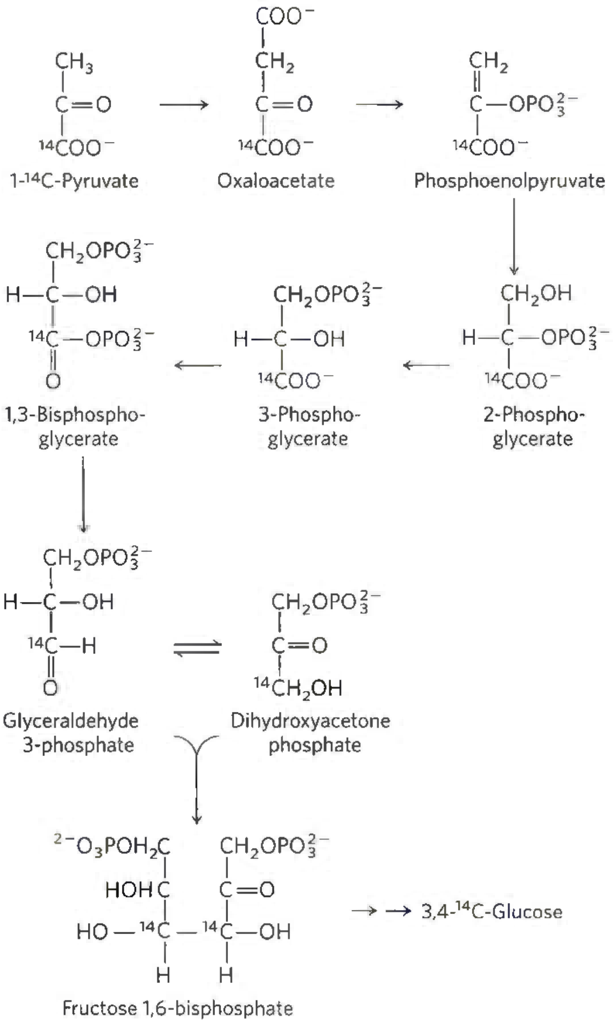
23. Fermentation releases energy, some conserved in the form of ATP but much of it dissipated as heat. Unless the fermenter contents are cooled, the temperature would become high enough to kill the microorganisms.

24. Soybeans and wheat contain starch, a polymer of glucose. The microorganisms break down starch to glucose, glucose to pyruvate via glycolysis, and—because the process is carried out in the absence of O_2 (i.e., it is a fermentation)—pyruvate to lactate and ethanol. If O_2 were present, pyruvate would be oxidized to acetyl-CoA, then to CO_2 and H_2O. Some of the acetyl-CoA, however, would also be hydrolyzed to acetic acid (vinegar) in the presence of oxygen.

25. (a), **(b)**, and **(d)** are glucogenic; **(c)** and **(e)** are not.

26. (a) In the pyruvate carboxylase reaction, $^{14}CO_2$ is added to pyruvate, but PEP carboxykinase removes the *same* CO_2 in the next step. Thus, ^{14}C is not (initially) incorporated into glucose.

(b)



27. 4 ATP equivalents per glucose molecule

28. Gluconeogenesis would be highly endergonic, and it would be impossible to separately regulate gluconeogenesis and glycolysis.

29. The cell "spends" 1 ATP and 1 GTP in converting pyruvate to PEP.

30. The proteins are degraded to amino acids and used for gluconeogenesis.

31. Succinate transforms to oxaloacetate, which passes into the cytosol and is converted to PEP by PEP carboxykinase. Two moles of PEP are then required to produce a mole of glucose by the route outlined in Fig. 14-16.

32. If the catabolic and anabolic pathways of glucose metabolism are operating simultaneously, unproductive cycling of ADP and ATP occurs, with extra O_2 consumption.

33. At the very least, accumulation of ribose 5-phosphate would tend to force this reaction in the reverse direction by mass action (see Eqn 13-4). It might also affect other metabolic reactions that involve ribose 5-phosphate as a substrate or product—such as the pathways of nucleotide synthesis.

34. (a) Ethanol tolerance is likely to involve many more genes, and thus the engineering would be a much more involved project. **(b)** L-Arabinose isomerase (the *araA* enzyme) converts an aldose to a ketose by moving the carbonyl of a nonphosphorylated sugar from C-1 to C-2. No analogous enzyme is discussed in this chapter; all the enzymes described here act on phosphorylated sugars. An enzyme that carries out a similar transformation with phosphorylated sugars is phosphohexose isomerase. L-Ribulokinase (*araB*) phosphorylates a sugar at C-5 by transferring the γ phosphate from ATP. Many such reactions are described in this chapter, including the hexokinase reaction. L-Ribulose 5-phosphate epimerase (*araD*) switches the —H and —OH groups on a chiral carbon of a sugar. No analogous reaction is described in the chapter, but it is described in Chapter 20 (see Fig. 20-31). **(c)** The three *ara* enzymes would convert arabinose to xylulose 5-phosphate by the following pathway: Arabinose $\xrightarrow{\text{L-arabinose isomerase}}$ L-ribulose $\xrightarrow{\text{L-ribulokinase}}$ 5-phosphate $\xrightarrow{\text{epimerase}}$ xylulose 5-phosphate. **(d)** The arabinose is converted to xylulose 5-phosphate as in (c), which enters the pathway in Fig. 14-31a; the glucose 6-phosphate product is then fermented to ethanol and CO_2. **(e)** 6 molecules of arabinose + 6 molecules of ATP are converted to 6 molecules of xylulose 5-phosphate, which feed into the pathway in Fig. 14-31a to yield 5 molecules of glucose 6-phosphate, each of which is fermented to yield 3 ATP (they enter as glucose 6-phosphate, not glucose)—15 ATP in all. Overall, you would expect a yield of 15 ATP − 6 ATP = 9 ATP from the 6 arabinose molecules. The other products are 10 molecules of ethanol and 10 molecules of CO_2. **(f)** Given the lower ATP yield, for an amount of growth (i.e., of available ATP) equivalent to growth without the added genes, the engineered *Z. mobilis* must ferment more arabinose, and thus it produces more ethanol. **(g)** One way to allow the use of xylose would be to add the genes for two enzymes: an analog of the *araD* enzyme that converts xylose to ribose by switching the —H and —OH on C-3, and an analog of the *araB* enzyme that phosphorylates ribose at C-5. The resulting ribose 5-phosphate would feed into the existing pathway.

Chapter 15

1. 11 s

2. (a) *In muscle:* Glycogen breakdown supplies energy (ATP) via glycolysis. Glycogen phosphorylase catalyzes the conversion of stored glycogen to glucose 1-phosphate, which is converted to glucose 6-phosphate, an intermediate in glycolysis. During strenuous activity, skeletal muscle requires large quantities of glucose 6-phosphate. *In the liver:* Glycogen breakdown maintains a steady level of blood glucose between meals (glucose 6-phosphate is converted to free glucose). **(b)** In actively working muscle, ATP flux requirements are very high and glucose 1-phosphate must be produced rapidly, requiring a high V_{max}.

3. (a) 3.5/1 **(b)**, **(c)** The value of this ratio in the cell (>100:1) indicates that [glucose 1-phosphate] is far below the equilibrium value. The rate at which glucose 1-phosphate is removed (through entry into glycolysis) is greater than its rate of production (by the glycogen phosphorylase reaction), so metabolite flow is from glycogen to glucose 1-phosphate. The glycogen phosphorylase reaction is probably the regulatory step in glycogen breakdown.

4. (a) Increases **(b)** Decreases **(c)** Increases

5. *Resting:* [ATP] high; [AMP] low; [acetyl-CoA] and [citrate] intermediate. *Running:* [ATP] intermediate; [AMP] high; [acetyl-CoA] and [citrate] low. Glucose flux through glycolysis increases during the anaerobic sprint because (1) the ATP inhibition of glycogen phosphorylase and PFK-1 is partially relieved, (2) AMP stimulates both enzymes, and (3) lower citrate and acetyl-CoA levels relieve their inhibitory effects on PFK-1 and pyruvate kinase, respectively.

6. The migrating bird relies on the highly efficient aerobic oxidation of fats, rather than the anaerobic metabolism of glucose used by a sprinting rabbit. The bird reserves its muscle glycogen for short bursts of energy during emergencies.

7. *Case A:* (f), (3); *Case B:* (c), (3); *Case C:* (h), (4); *Case D:* (d), (6)

8. (a) (1) Adipose: fatty acid synthesis slower. (2) Muscle: glycolysis, fatty acid synthesis, and glycogen synthesis slower. (3) Liver: glycolysis faster; gluconeogenesis, glycogen synthesis, and fatty acid synthesis slower; pentose phosphate pathway unchanged. **(b)** (1) Adipose and (3) liver: fatty acid synthesis slower because lack of insulin results in inactive acetyl-CoA carboxylase, the first enzyme of fatty acid synthesis. Glycogen synthesis inhibited by cAMP-dependent phosphorylation (thus activation) of glycogen synthase. (2) Muscle: glycolysis slower because GLUT4 is inactive, so glucose uptake is inhibited. (3) Liver: glycolysis slower because the bifunctional PFK-2/FBPase-2 is converted to the form with active FBPase-2, decreasing [fructose 2,6-bisphosphate], which allosterically stimulates phosphofructokinase and inhibits FBPase-1; this also accounts for the stimulation of gluconeogenesis.

9. (a) Elevated **(b)** Elevated **(c)** Elevated

10. (a) PKA cannot be activated in response to glucagon or epinephrine, and glycogen phosphorylase is not activated. **(b)** PP1 remains active, allowing it to dephosphorylate glycogen synthase (activating it) and glycogen phosphorylase (inhibiting it). **(c)** Phosphorylase remains phosphorylated (active), increasing the breakdown of glycogen. **(d)** Gluconeogenesis cannot be stimulated when blood glucose is low, leading to dangerously low blood glucose during periods of fasting.

11. The drop in blood glucose triggers release of glucagon by the pancreas. In the liver, glucagon activates glycogen phosphorylase by stimulating its cAMP-dependent phosphorylation and stimulates gluconeogenesis by lowering [fructose 2,6-bisphosphate], thus stimulating FBPase-1.

12. (a) Reduced capacity to mobilize glycogen; lowered blood glucose between meals **(b)** Reduced capacity to lower blood glucose after a carbohydrate meal; elevated blood glucose **(c)** Reduced concentration of fructose 2,6-bisphosphate (F26BP) in liver, stimulating glycolysis and inhibiting gluconeogenesis **(d)** Reduced [F26BP], stimulating gluconeogenesis and inhibiting glycolysis **(e)** Increased uptake of fatty acids and glucose; increased oxidation of both **(f)** Increased conversion of pyruvate to acetyl-CoA; increased fatty acid synthesis

13. (a) Given that each particle contains about 55,000 glucose residues, the equivalent free glucose concentration would be $55{,}000 \times 0.01\ \mu\text{M} = 550\ \text{mM}$, or 0.55 M. This would present a serious osmotic challenge for the cell! (Body fluids have a substantially lower osmolarity.) **(b)** The lower the number of branches, the lower the number of free ends available for glycogen phosphorylase activity, and the slower the rate of glucose release. With no branches, there would be just one site for phosphorylase to act. **(c)** The outer tier of the particle would be too crowded with glucose residues for the enzyme to gain access to cleave bonds and release glucose. **(d)** The number of chains doubles in each succeeding tier: tier 1 has one chain (2^0), tier 2 has two (2^1), tier 3 has four (2^2), and so on. Thus, for t tiers, the number of chains in the outermost tier, C_A, is 2^{t-1}. **(e)** The total number of chains is $2^0 + 2^1 + 2^2 + \ldots 2^{t-1} = 2^t - 1$. Each chain contains g_c glucose molecules, so the total number of glucose molecules, G_T, is $g_c(2t - 1)$. **(f)** Glycogen phosphorylase can release all but four of the glucose residues in a chain of length g_c. Therefore, from each chain in the outer tier it can release $(g_c - 4)$ glucose molecules. Given that there are 2^{t-1} chains in the outer tier, the number of glucose molecules the enzyme can release, G_{PT}, is $(g_c - 4)(2^{t-1})$. **(g)** The volume of a sphere is $\frac{4}{3}\pi r^3$. In this case, r is the thickness of one tier times the number of tiers, or $(0.12g_c + 0.35)t$ nm. Thus $V_s = \frac{4}{3}\pi t^3(0.12g_c + 0.35)^3\ \text{nm}^3$. **(h)** You can show algebraically that the value of g_c that maximizes f is independent of t. Choosing $t = 7$:

g_c	C_A	G_T	G_{PT}	V_S	f
5	64	635	64	1,232	2,111
6	64	762	128	1,760	3,547
7	64	889	192	2,421	4,512
8	64	1,016	256	3,230	5,154
9	64	1,143	320	4,201	5,572
10	64	1,270	384	5,350	5,834
11	64	1,397	448	6,692	5,986
12	64	1,524	512	8,240	6,060
13	64	1,651	576	10,011	6,079
14	64	1,778	640	12,019	6,059
15	64	1,905	704	14,279	6,011
16	64	2,032	768	16,806	5,943

Note: The optimum value of g_c (i.e., at maximum f) is 13. In nature, g_c varies from 12 to 14, which corresponds to f values very close to the optimum. If you choose another value for t, the numbers will differ but the optimal g_c will still be 13.

Chapter 16

1. (a)

❶ *Citrate synthase:*
Acetyl-CoA + oxaloacetate + H_2O → citrate + CoA
❷ *Aconitase:*
Citrate → isocitrate
❸ *Isocitrate dehydrogenase:*
Isocitrate + NAD^+ → α-ketoglutarate + CO_2 + NADH
❹ *α-Ketoglutarate dehydrogenase:*
α-Ketoglutarate + NAD^+ + CoA → succinyl-CoA + CO_2 + NADH
❺ *Succinyl-CoA synthetase:*
Succinyl-CoA + P_i + GDP → succinate + CoA + GTP
❻ *Succinate dehydrogenase:*
Succinate + FAD → fumarate + $FADH_2$
❼ *Fumarase:*
Fumarate + H_2O → malate
❽ *Malate dehydrogenase:*
Malate + NAD^+ → oxaloacetate + NADH + H^+

(b), (c) ❶ CoA, condensation; ❷ none, isomerization; ❸ NAD^+, oxidative decarboxylation; ❹ NAD^+, CoA, and thiamine pyrophosphate, oxidative decarboxylation; ❺ CoA, substrate-level phosphorylation; ❻ FAD, oxidation; ❼ none, hydration; ❽ NAD^+, oxidation

(d) $\text{Acetyl-CoA} + 3\text{NAD}^+ + \text{FAD} + \text{GDP} + \text{P}_i + 2\text{H}_2\text{O} \rightarrow 2\text{CO}_2 + \text{CoA} + 3\text{NADH} + \text{FADH}_2 + \text{GTP} + 2\text{H}^+$

2. $\text{Glucose} + 4\text{ADP} + 4\text{P}_i + 10\text{NAD}^+ + 2\text{FAD} \rightarrow 4\text{ATP} + 10\text{NADH} + 2\text{FADH}_2 + 6\text{CO}_2$

3. (a) Oxidation; methanol → formaldehyde + [H—H]

(b) Oxidation; formaldehyde + H_2O → formate + [H—H]

(c) Reduction; CO_2 + [H—H] → formate + H^+

(d) Reduction; glycerate + H^+ + [H—H] → glyceraldehyde + H_2O

(e) Oxidation; glycerol → dihydroxyacetone + [H—H]

(f) Oxidation; $2H_2O$ + toluene → benzoate + H^+ + 3[H—H]

(g) Oxidation; succinate → fumarate + [H—H]

(h) Oxidation; pyruvate + H_2O → acetate + CO_2 + [H—H]

4. From the structural formulas, we see that the carbon-bound H/C ratio of hexanoate (11/6) is higher than that of glucose (7/6). Hexanoate is more reduced and yields more energy on complete combustion to CO_2 and H_2O.

5. (a) Oxidized; ethanol + NAD^+ → acetaldehyde + NADH + H^+

(b) Reduced; 1,3-bisphosphoglycerate + NADH + H^+ →
glyceraldehyde 3-phosphate + NAD^+ + HPO_4^{2-}

(c) Unchanged; pyruvate + H^+ → acetaldehyde + CO_2

(d) Oxidized; pyruvate + NAD^+ → acetate + CO_2 + NADH + H^+

(e) Reduced; oxaloacetate + NADH + H^+ → malate + NAD^+

(f) Unchanged; acetoacetate + H^+ → acetone + CO_2

6. *TPP:* thiazolium ring adds to α carbon of pyruvate, then stabilizes the resulting carbanion by acting as an electron sink. *Lipoic acid:* oxidizes pyruvate to level of acetate (acetyl-CoA) and activates acetate as a thioester. *CoA-SH:* activates acetate as thioester. *FAD:* oxidizes lipoic acid. *NAD^+:* oxidizes $FADH_2$.

7. Lack of TPP, caused by thiamine deficiency, inhibits pyruvate dehydrogenase; pyruvate accumulates.

8. Oxidative decarboxylation; NAD^+ or $NADP^+$; α-ketoglutarate dehydrogenase reaction

9. Oxygen consumption is a measure of the activity of the first two stages of cellular respiration: glycolysis and the citric acid cycle. The addition of oxaloacetate or malate stimulates the citric acid cycle and thus stimulates respiration. The added oxaloacetate or malate serves a catalytic role: it is regenerated in the latter part of the citric acid cycle.

10. (a) 5.6×10^{-6} **(b)** 1.1×10^{-8} M **(c)** 28 molecules

11. ADP (or GDP), P_i, CoA-SH, TPP, NAD^+; *not* lipoic acid, which is covalently attached to the isolated enzymes that use it

12. The flavin nucleotides, FMN and FAD, would not be synthesized. Because FAD is required in the citric acid cycle, flavin deficiency would strongly inhibit the cycle.

13. Oxaloacetate might be withdrawn for aspartate synthesis or for gluconeogenesis. Oxaloacetate is replenished by the anaplerotic reactions catalyzed by PEP carboxykinase, PEP carboxylase, malic enzyme, or pyruvate carboxylase (see Fig. 16-15).

14. The terminal phosphoryl group of GTP can be transferred to ADP in a reaction catalyzed by nucleoside diphosphate kinase, with an equilibrium constant of 1.0: GTP + ADP → GDP + ATP.

15. (a) $^-OOC—CH_2—CH_2—COO^-$ (succinate) **(b)** Malonate is a competitive inhibitor of succinate dehydrogenase. **(c)** A block in the citric acid cycle stops NADH formation, which stops electron transfer, which stops respiration. **(d)** A large excess of succinate (substrate) overcomes the competitive inhibition.

16. (a) Add uniformly labeled [^{14}C]glucose and check for the release of $^{14}CO_2$. **(b)** Equally distributed in C-2 and C-3 of oxaloacetate; an infinite number of turns

17. (a) C-1 **(b)** C-3 **(c)** C-3 **(d)** C-2 (methyl group) **(e)** C-4 **(f)** C-4 **(g)** Equally distributed in C-2 and C-3

18. Thiamine is required for the synthesis of TPP, a prosthetic group in the pyruvate dehydrogenase and α-ketoglutarate dehydrogenase complexes. A thiamine deficiency reduces the activity of these enzyme complexes and causes the observed accumulation of precursors.

19. No. For every two carbons that enter as acetate, two leave the cycle as CO_2; thus there is no net synthesis of oxaloacetate. Net synthesis of oxaloacetate occurs by the carboxylation of pyruvate, an anaplerotic reaction.

20. Yes. The citric acid cycle would be inhibited. Oxaloacetate is present at relatively low concentrations in mitochondria, and removing it for gluconeogenesis would tend to shift the equilibrium for the citrate synthase reaction toward oxaloacetate.

21. (a) Inhibition of aconitase **(b)** Fluorocitrate; competes with citrate; by a large excess of citrate **(c)** Citrate and fluorocitrate are inhibitors of PFK-1. **(d)** All catabolic processes necessary for ATP production are shut down.

22. *Glycolysis:*

Glucose + $2P_i$ + 2ADP + $2NAD^+$ →
2 pyruvate + 2ATP + 2NADH + $2H^+$ + $2H_2O$

Pyruvate carboxylase reaction:

2 Pyruvate + $2CO_2$ + 2ATP + $2H_2O$ →
2 oxaloacetate + 2ADP + $2P_i$ + $4H^+$

Malate dehydrogenase reaction:

2 Oxaloacetate + 2NADH + $2H^+$ → 2 L-malate + $2NAD^+$

This sequence recycles nicotinamide coenzymes under anaerobic conditions. The overall reaction is glucose + $2CO_2$ → 2 L-malate + $4H^+$. Four H^+ are produced per glucose, increasing the acidity and thus the tartness of the wine.

23. Pyruvate + ATP + CO_2 + H_2O → oxaloacetate + ADP + P_i + H^+
Pyruvate + CoA + NAD^+ → acetyl-CoA + CO_2 + NADH + H^+
Oxaloacetate + acetyl-CoA → citrate + CoA
Citrate → isocitrate
Isocitrate + NAD^+ → α-ketoglutarate + CO_2 + NADH + H^+
Net reaction: 2 Pyruvate + ATP + $2NAD^+$ + H_2O →
α-ketoglutarate + CO_2 + ADP + P_i + 2NADH + $3H^+$

24. The cycle participates in catabolic and anabolic processes. For example, it generates ATP by substrate oxidation, but also provides precursors for amino acid synthesis (see Fig. 16-15).

25. (a) Decreases **(b)** Increases **(c)** Decreases

26. (a) Citrate is produced through the action of citrate synthase on oxaloacetate and acetyl-CoA. Citrate synthase can be used for net synthesis of citrate when (1) there is a continuous influx of new oxaloacetate and acetyl-CoA and (2) isocitrate synthesis is restricted, as in a culture medium low in Fe^{3+}. Aconitase requires Fe^{3+}, so an Fe^{3+}-restricted medium restricts the synthesis of aconitase.

(b) Sucrose + H_2O → glucose + fructose

Glucose + $2P_i$ + 2ADP + $2NAD^+$ →
2 pyruvate + 2ATP + 2NADH + $2H^+$ + $2H_2O$

Fructose + $2P_i$ + 2ADP + $2NAD^+$ →
2 pyruvate + 2ATP + 2NADH + $2H^+$ + $2H_2O$

2 Pyruvate + $2NAD^+$ + 2CoA →
2 acetyl-CoA + 2NADH + $2H^+$ + $2CO_2$

2 Pyruvate + $2CO_2$ + 2ATP + $2H_2O$ →
2 oxaloacetate + 2ADP + $2P_i$ + $4H^+$

2 Acetyl-CoA + 2 oxaloacetate + $2H_2O$ → 2 citrate + 2CoA

The overall reaction is

Sucrose + H_2O + $2P_i$ + 2ADP + $6NAD^+$ →
2 citrate + 2ATP + 6NADH + $10H^+$

(c) The overall reaction consumes NAD^+. Because the cellular pool of this oxidized coenzyme is limited, it must be regenerated from NADH by the electron-transfer chain, with consumption of O_2. Consequently, the overall conversion of sucrose to citric acid is an aerobic process and requires molecular oxygen.

27. Succinyl-CoA is an intermediate of the citric acid cycle; its accumulation signals reduced flux through the cycle, calling for reduced entry of acetyl-CoA into the cycle. Citrate synthase, by regulating the primary oxidative pathway of the cell, regulates the supply of NADH and thus the flow of electrons from NADH to O_2.

28. Fatty acid catabolism increases [acetyl-CoA], which stimulates pyruvate carboxylase. The resulting increase in [oxaloacetate] stimulates acetyl-CoA consumption by the citric acid cycle, and [citrate] rises, inhibiting glycolysis at the level of PFK-1. In addition, increased [acetyl-CoA] inhibits the pyruvate dehydrogenase complex, slowing the utilization of pyruvate from glycolysis.

29. Oxygen is needed to recycle NAD$^+$ from the NADH produced by the oxidative reactions of the citric acid cycle. Reoxidation of NADH occurs during mitochondrial oxidative phosphorylation.

30. Increased [NADH]/[NAD$^+$] inhibits the citric acid cycle by mass action at the three NAD$^+$-reducing steps; high [NADH] shifts the equilibrium toward NAD$^+$.

31. Toward citrate; ΔG for the citrate synthase reaction under these conditions is about −8 kJ/mol.

32. Steps ④ and ⑤ are essential in the reoxidation of the enzyme's reduced lipoamide cofactor.

33. Many answers are possible. A genetic defect in *MPC1* or *MPC2* switches pyruvate catabolism from the oxidative path (through acetyl-CoA and the citric acid cycle) to the anaerobic reduction of pyruvate to lactate, with a much-increased use of glucose for the glycolytic production of ATP. The increase in cytosolic lactate concentration would acidify that part of the cell. Citric acid cycle activity would slow or would draw on substrates other than glycolytic pyruvate, such as fatty acids from adipose tissue. Blood levels of pyruvate and lactate would rise and blood pH would drop, producing acidosis. Muscle would fatigue easily.

34. The citric acid cycle is so central to metabolism that a serious defect in any cycle enzyme would probably be lethal to the embryo.

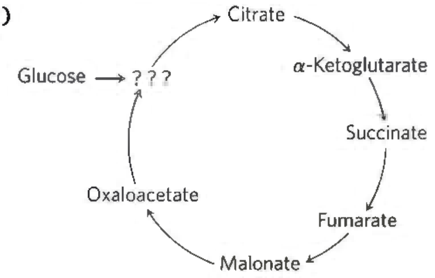
35. (a) The only reaction in muscle tissue that consumes significant amounts of oxygen is cellular respiration, so O_2 consumption is a good proxy for respiration. **(b)** Freshly prepared muscle tissue contains some residual glucose; O_2 consumption is due to oxidation of this glucose. **(c)** Yes. Because the amount of O_2 consumed increased when citrate or 1-phosphoglycerol was added, both can serve as substrate for cellular respiration in this system. **(d)** *Experiment I:* Citrate is causing much more O_2 consumption than would be expected from its complete oxidation. Each molecule of citrate seems to be acting as though it were more than one molecule. The only possible explanation is that each molecule of citrate functions more than once in the reaction—which is how a catalyst operates. *Experiment II:* The key is to calculate the excess O_2 consumed by each sample compared with the control (sample 1).

Sample	Substrate(s) added	μL O_2 absorbed	Excess μL O_2 consumed
1	No extra	342	0
2	0.3 mL 0.2 M 1-phosphoglycerol	757	415
3	0.15 mL 0.02 M citrate	431	89
4	0.3 mL 0.2 M 1-phosphoglycerol + 0.15 mL 0.02 M citrate	1,385	1,043

If both citrate and 1-phosphoglycerol were simply substrates for the reaction, you would expect the excess O_2 consumption by sample 4 to be the sum of the individual excess consumptions by samples 2 and 3 (415 μL + 89 μL = 504 μL). However, the excess consumption when both substrates are present is roughly twice this amount (1,043 μL). Thus citrate increases the ability of the tissue to metabolize 1-phosphoglycerol. This behavior is typical of a catalyst. Both experiments (I and II) are required to make this case convincing. Based on experiment I only, citrate is somehow accelerating the reaction, but it is not clear whether it acts by helping substrate metabolism or by some other mechanism. Based on experiment II only, it is not clear which molecule is the catalyst, citrate or 1-phosphoglycerol. Together, the experiments show that citrate is acting as a "catalyst" for the oxidation of 1-phosphoglycerol.

(e) Given that the pathway can consume citrate (see sample 3), if citrate is to act as a catalyst it must be regenerated. If the set of reactions first consumes then regenerates citrate, it must be a circular rather than a linear pathway. **(f)** When the pathway is blocked at α-ketoglutarate dehydrogenase, citrate is converted to α-ketoglutarate but the pathway goes no further. Oxygen is consumed by reoxidation of the NADH produced by isocitrate dehydrogenase.

(g)



This differs from Fig. 16-7 in that it does not include *cis*-aconitate and isocitrate (between citrate and α-ketoglutarate), or succinyl-CoA, or acetyl-CoA. **(h)** Establishing a quantitative conversion was essential to rule out a branched or other, more complex pathway.

Chapter 17

1. The fatty acid portion; the carbons in fatty acids are more reduced than those in glycerol.

2. Response to glucagon or epinephrine would be prolonged, mobilizing more fatty acids in adipocytes.

3. Fatty acyl groups condensed with CoA in the cytosol are first transferred to carnitine, releasing CoA, then transported into the mitochondrion, where they are again condensed with CoA. The cytosolic and mitochondrial pools of CoA are thus kept separate, and no radioactive CoA from the cytosolic pool enters the mitochondrion.

4. Malonyl-CoA would no longer inhibit entry of fatty acids into the mitochondrion for β oxidation, so there might be a futile cycle of simultaneous fatty acid synthesis in the cytosol and fatty acid breakdown in mitochondria.

5. (a) The carnitine-mediated entry of fatty acids into mitochondria is the rate-limiting step in fatty acid oxidation. Carnitine deficiency slows fatty acid oxidation; added carnitine increases the rate. **(b)** All increase the metabolic need for fatty acid oxidation. **(c)** Carnitine deficiency might result from a deficiency of a carnitine precursor (such as lysine), or from a defect in one of the enzymes in the biosynthesis of carnitine.

6. (a) 4.0×10^5 kJ (9.6×10^4 kcal) **(b)** 48 days **(c)** 0.48 lb/day

7. The first step in fatty acid oxidation is analogous to the conversion of succinate to fumarate; the second step, to the conversion of fumarate to malate; the third step, to the conversion of malate to oxaloacetate.

8. 8 cycles; the last releases 2 acetyl-CoA.

9. (a) R—COO$^-$ + ATP $\rightarrow$ acyl-AMP + PP$_i$
Acyl-AMP + CoA $\rightarrow$ acyl-CoA + AMP

(b) Irreversible hydrolysis of PP$_i$ to 2P$_i$ by cellular inorganic pyrophosphatase

10. *cis*-Δ^3-Dodecanoyl-CoA; it is converted to *cis*-Δ^2-dodecanoyl-CoA, then β-hydroxydodecanoyl-CoA.

11. 4 acetyl-CoA and 1 propionyl-CoA

12. Yes. Some of the tritium is removed from palmitate during the dehydrogenation reactions of β oxidation. The removed tritium appears as tritiated water.

13. (a) In the pigeon, β oxidation predominates; in the pheasant, anaerobic glycolysis of glycogen predominates. **(b)** Pigeon muscle would consume more O_2. **(c)** Fat contains more energy per gram than glycogen does. In addition, the anaerobic breakdown of glycogen is limited by the tissue's tolerance to lactate buildup. Thus the pigeon, using the oxidative catabolism of fats, is the long-distance flyer. **(d)** The enzymes listed in the table are the regulatory enzymes of their respective pathways and thus limit ATP production rate; however, triose phosphate isomerase and malate dehydrogenase are not regulatory enzymes of their respective pathways.

14. Oxidation of fats releases metabolic water; 1.5 L of water per kg of tripalmitoylglycerol (ignores the small contribution of glycerol to the mass).

15. (a) M_r 136; phenylacetic acid **(b)** Even; removal of two carbons at a time from odd-number chains would leave phenylpropionate.

16. Because the mitochondrial pool of CoA is small, CoA must be recycled from acetyl-CoA via the formation of ketone bodies. This allows the operation of the β-oxidation pathway, necessary for energy production.

17. (a) Glucose yields pyruvate via glycolysis, and pyruvate is the main source of oxaloacetate. Without glucose in the diet, [oxaloacetate] drops and the citric acid cycle slows. **(b)** Odd-number; propionate conversion to succinyl-CoA provides intermediates for the citric acid cycle and four-carbon precursors for gluconeogenesis.

18. For the odd-number heptanoic acid, β oxidation produces propionyl-CoA, which can be converted in several steps to oxaloacetate, a starting material for gluconeogenesis. The even-number fatty acid cannot support gluconeogenesis, because it is entirely oxidized to acetyl-CoA.

19. β Oxidation of ω-fluorooleate forms fluoroacetyl-CoA, which enters the citric acid cycle and produces fluorocitrate, a powerful inhibitor of aconitase. Inhibition of aconitase shuts down the citric acid cycle. Without reducing equivalents from the citric acid cycle, oxidative phosphorylation (ATP synthesis) is fatally slowed.

20. Ser to Ala: the Ala side chain in ACC cannot be phosphorylated (and thereby inactivated). Malonyl-CoA continues to be made, which inhibits carnitine acyltransferase 1. β oxidation in mitochondria is blocked. Ser to Asp: ACC has a negative charge where Ser would normally be phosphorylated, so it remains inactive. Fatty acid synthesis is blocked and β oxidation is stimulated (derepressed).

21. Enz-FAD, having a more positive standard reduction potential, is a better electron acceptor than NAD^+, and the reaction is driven in the direction of fatty acyl–CoA oxidation. This more favorable equilibrium is obtained at the cost of 1 ATP; only 1.5 ATP are produced per $FADH_2$ oxidized in the respiratory chain (vs. 2.5 per NADH).

22. 9 turns; arachidic acid, a 20-carbon saturated fatty acid, yields 10 molecules of acetyl-CoA, the last two formed in the ninth turn.

23. See Fig. 17-12. [3-^{14}C]Succinyl-CoA is formed, which gives rise to oxaloacetate labeled at C-2 and C-3.

24. Phytanic acid → pristanic acid → propionyl-CoA →→→ succinyl-CoA → succinate → fumarate → malate. All malate carbons would be labeled, but C-1 and C-4 would have only half as much label as C-2 and C-3.

25. ATP hydrolysis in the energy-requiring reactions of a cell takes up water in the reaction $ATP + H_2O \rightarrow ADP + P_i$; thus, in the steady state, there is no *net* production of H_2O.

26. Digestion of propionate requires methylmalonyl-CoA mutase, which, in turn, requires the cobalt-containing cofactor formed from vitamin B_{12}.

27. Mass lost per day is about 0.66 kg, or about 140 kg in seven months. Ketosis could be avoided by degradation of nonessential body proteins to supply amino acid skeletons for gluconeogenesis.

28. (a) Fatty acids are converted to their CoA derivatives by enzymes in the cytoplasm; the acyl-CoAs are then imported into mitochondria for oxidation. Given that the researchers were using isolated mitochondria, they had to use CoA derivatives. **(b)** Stearoyl-CoA was rapidly converted to 9 acetyl-CoA by the β-oxidation pathway. All intermediates reacted rapidly, and none were detectable at significant levels. **(c)** Two rounds. Each round removes two carbon atoms, thus two rounds convert an 18-carbon to a 14-carbon fatty acid and 2 acetyl-CoA. **(d)** The K_m is higher for the trans isomer than for the cis, so a higher concentration of trans isomer is required for the same rate of breakdown. Roughly speaking, the trans isomer binds less well than the cis, probably because differences in shape, even though not at the target site for the enzyme, affect substrate binding to the enzyme. **(e)** The substrate for LCAD/VLCAD builds up differently, depending on the particular substrate; this is expected for the rate-limiting step in a pathway. **(f)** The kinetic parameters show that the trans isomer is a poorer substrate than the cis for LCAD, but there is little difference for VLCAD. Because it is a poorer substrate, the trans isomer accumulates to higher levels than the cis. **(g)** One possible pathway is shown below (indicating "inside" and "outside" mitochondria).

$$\underset{\text{(outside)}}{\text{Elaidoyl-CoA}} \xrightarrow{\text{carnitine acyltransferase 1}} \underset{\text{(outside)}}{\text{elaidoyl-carnitine}} \xrightarrow{\text{transport}}$$

$$\underset{\text{(inside)}}{\text{elaidoyl-carnitine}} \xrightarrow{\text{carnitine acyltransferase 2}} \underset{\text{(inside)}}{\text{elaidoyl-CoA}} \xrightarrow{\text{2 rounds of } \beta \text{ oxidation}}$$

$$\underset{\text{(inside)}}{\text{5-}\textit{trans}\text{-tetradecenoyl-CoA}} \xrightarrow{\text{thioesterase}} \underset{\text{(inside)}}{\text{5-}\textit{trans}\text{-tetradecanoic acid}} \xrightarrow{\text{diffusion}}$$

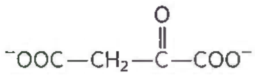
$$\underset{\text{(outside)}}{\text{5-}\textit{trans}\text{-tetradecanoic acid}}$$

(h) It is correct insofar as trans fats are broken down less efficiently than cis fats, and thus trans fats may "leak" out of mitochondria. It is incorrect to say that trans fats are not broken down by cells; they are broken down, but at a slower rate than cis fats.

Chapter 18

1.

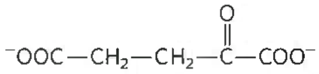
(a)



$$^{-}OOC{-}CH_2{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}COO^{-}$$

Oxaloacetate

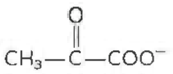
(b)



$$^{-}OOC{-}CH_2{-}CH_2{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}COO^{-}$$

α-Ketoglutarate

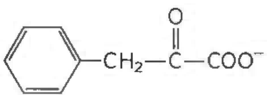
(c)



$$CH_3{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}COO^{-}$$

Pyruvate

(d)



Phenylpyruvate

2. This is a coupled-reaction assay. The product of the slow transamination (pyruvate) is rapidly consumed in the subsequent "indicator reaction" catalyzed by lactate dehydrogenase, which consumes NADH. Thus the rate of disappearance of NADH is a measure of the rate of the aminotransferase reaction. The indicator reaction is monitored by observing the decrease in absorption of NADH at 340 nm with a spectrophotometer.

3. Alanine and glutamine play special roles in the transport of amino groups from muscle and from other nonhepatic tissues, respectively, to the liver.

4. GTP is a product of the citric acid cycle, generated in the second step after the formation of α-ketoglutarate. Elimination of the

GTP inhibition of glutamate dehydrogenase leads to uncon
production of α-ketoglutarate, which is oxidized to produc
levels of ATP. This in turn leads to insulin secretion.

5. No. The nitrogen in alanine can be transferred to oxaloa
transamination, to form aspartate.

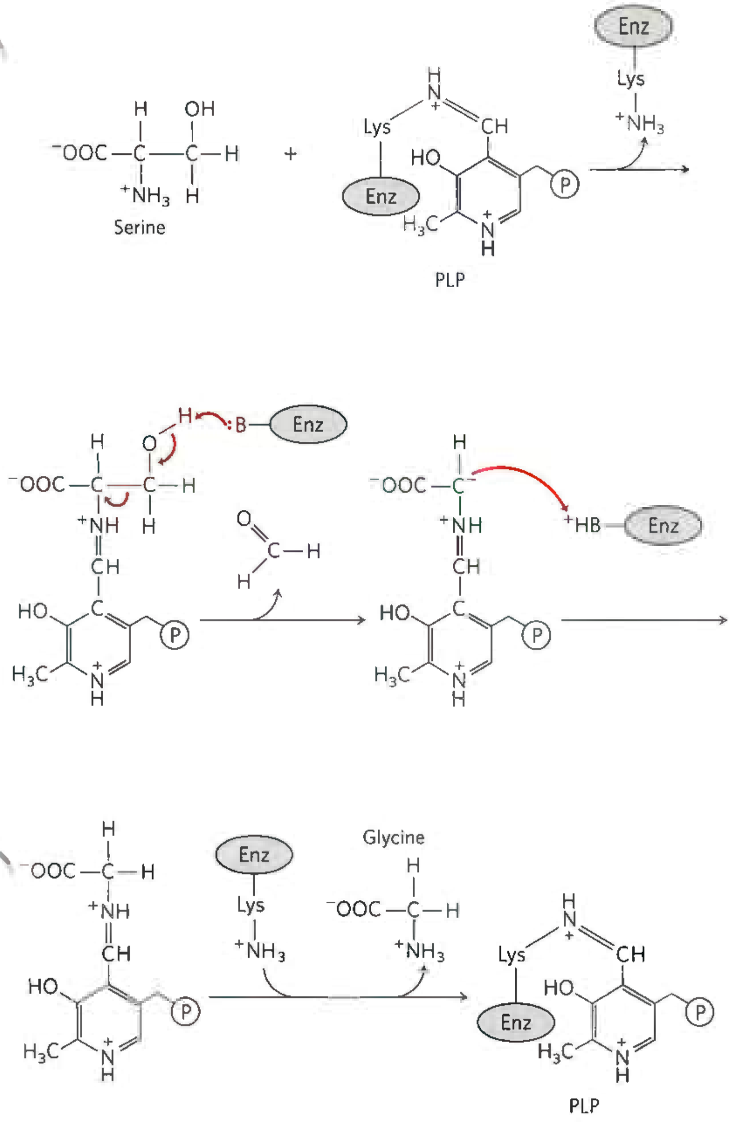
6. 15 mol of ATP per mol of lactate; 13 mol of ATP per mol
when nitrogen removal is included

7. **(a)** Fasting resulted in low blood glucose; subsequent
administration of the experimental diet led to rapid catab
of glucogenic amino acids. **(b)** Oxidative deamination ca
rise in NH_3 levels; the absence of arginine (an intermedia
urea cycle) prevented conversion of NH_3 to urea; arginin
synthesized in sufficient quantities in the cat to meet the
imposed by the stress of the experiment. This suggests t
is an essential amino acid in the cat's diet. **(c)** Ornithine
to arginine by the urea cycle.

8. H_2O + glutamate + NAD^+ → α-ketoglutarate + NH_4^+ + N

[redacted]

19. A likely mechanism is



The formaldehyde (HCHO) produced in the second step reacts rapidly with tetrahydrofolate at the enzyme active site to produce N^5,N^{10}-methylenetetrahydrofolate (see Fig. 18-17).

20. (a) Transamination; no analogies; PLP **(b)** Oxidative decarboxylation; analogous to oxidative decarboxylation of pyruvate to acetyl-CoA prior to entry into the citric acid cycle, and of α-ketoglutarate to succinyl-CoA in the citric acid cycle; NAD^+, FAD, lipoate, and TPP **(c)** Dehydrogenation (oxidation); analogous to dehydrogenation of succinate to fumarate in the citric acid cycle, and of fatty acyl–CoA to enoyl-CoA in β oxidation; FAD **(d)** Carboxylation; no analogies in citric acid cycle or β oxidation; ATP and biotin **(e)** Hydration; analogous to hydration of fumarate to malate in the citric acid cycle, and of enoyl-CoA to 3-hydroxyacyl-CoA in β oxidation; no cofactors **(f)** Reverse aldol reaction; analogous to reverse of citrate synthase reaction in the citric acid cycle; no cofactors

21. Most amino acid catabolism occurs in the liver, including the key steps that are blocked in maple syrup urine disease. A liver transplant from a suitable donor with a normally functioning branched-chain α-keto acid dehydrogenase complex could alleviate disease symptoms.

22. (a) Leucine; valine; isoleucine **(b)** Cysteine (derived from cystine). If cysteine were decarboxylated as shown in Fig. 18-6, it would yield $H_3N—CH_2—CH_2—SH$, which could be oxidized to taurine. **(c)** The January 1957 blood shows significantly elevated levels of isoleucine, leucine, methionine, and valine; the January 1957 urine, significantly elevated isoleucine, leucine, taurine, and valine. **(d)** All patients had high levels of isoleucine, leucine, and valine in both blood and urine, suggesting a defect in the breakdown of these amino acids. Given that the urine also contained high levels of the keto forms of these three amino acids, the block in the pathway must occur after deamination but before dehydrogenation (as shown in Fig. 18-28). **(e)** The model does not explain the high levels of methionine in blood and taurine in urine. The high taurine levels may be due to the death of brain cells during the end stage of the disease. However, the reasons for high levels of methionine in blood are unclear; the pathway of methionine degradation is not linked with the degradation of branched-chain amino acids. Increased methionine could be a secondary effect of buildup of the other amino acids. It is important to keep in mind that the January 1957 samples were from an individual who was dying, so comparing blood and urine results with those of a healthy individual may not be appropriate. **(f)** The following information is needed (and was eventually obtained by other workers): (1) The dehydrogenase activity is significantly reduced or missing in individuals with maple syrup urine disease. (2) The disease is inherited as a single-gene defect. (3) The defect occurs in a gene encoding all or part of the dehydrogenase. (4) The genetic defect leads to production of inactive enzyme.

Chapter 19

1. *Reaction 1:* (a), (d) NADH; (b), (e) E-FMN; (c) $NAD^+/NADH$ and E-FMN/$FMNH_2$

Reaction 2: (a), (d) E-$FMNH_2$; (b), (e) Fe^{3+}; (c) E-FMN/$FMNH_2$ and Fe^{3+}/Fe^{2+}

Reaction 3: (a), (d) Fe^{2+}; (b), (e) Q; (c) Fe^{3+}/Fe^{2+} and Q/QH_2

2. The side chain makes ubiquinone soluble in lipids and allows it to diffuse in the semifluid membrane.

3. From the difference in standard reduction potential ($\Delta E'^\circ$) for each pair of half-reactions, we can calculate $\Delta G'^\circ$. The oxidation of succinate by FAD is favored by the negative standard free-energy change ($\Delta G'^\circ = -3.7$ kJ/mol). Oxidation by NAD^+ would require a large, positive, standard free-energy change ($\Delta G'^\circ = 68$ kJ/mol).

4. (a) All carriers reduced; CN^- blocks the reduction of O_2 catalyzed by cytochrome oxidase. **(b)** All carriers reduced; in the absence of O_2, the reduced carriers are not reoxidized. **(c)** All carriers oxidized **(d)** Early carriers more reduced; later carriers more oxidized

5. (a) Inhibition of NADH dehydrogenase by rotenone decreases the rate of electron flow through the respiratory chain, which in turn decreases the rate of ATP production. If this reduced rate is unable to meet the organism's ATP requirements, the organism dies. **(b)** Antimycin A strongly inhibits the oxidation of Q in the respiratory chain, reducing the rate of electron transfer and leading to the consequences described in (a). **(c)** Because antimycin A blocks *all* electron flow to oxygen, it is a more potent poison than rotenone, which blocks electron flow from NADH but not from $FADH_2$.

6. (a) The rate of electron transfer necessary to meet the ATP demand increases, and thus the P/O ratio decreases. **(b)** High concentrations of uncoupler produce P/O ratios near zero. The P/O ratio decreases and more fuel must be oxidized to generate the same amount of ATP. The extra heat released by this oxidation raises the body temperature. **(c)** Increased activity of the respiratory chain in the presence of an uncoupler requires the degradation of additional fuel. By oxidizing more fuel (including fat reserves) to produce the same amount of ATP, the body loses weight. When the P/O ratio approaches zero, the lack of ATP results in death.

7. Valinomycin acts as an uncoupler. It combines with K^+ to form a complex that passes through the inner mitochondrial membrane, dissipating the membrane potential. ATP synthesis decreases, which causes the rate of electron transfer to increase. This results in an increase in the H^+ gradient, O_2 consumption, and amount of heat released.

8. The steady-state concentration of P_i in the cell is much higher than that of ADP. The P_i released by ATP hydrolysis changes total $[P_i]$ very little.

9. Superoxide dismutase catalyzes the reduction of superoxide to hydrogen peroxide. The hydrogen peroxide can then be eliminated by glutathione peroxidase. This is a major pathway for eliminating the superoxide generated during respiration, helping to ameliorate the damaging effects of reactive oxygen species.

10. **(a)** External medium: 4.0×10^{-8} M; matrix: 2.0×10^{-8} M **(b)** $[H^+]$ gradient contributes 1.7 kJ/mol toward ATP synthesis. **(c)** 21 **(d)** No **(e)** From the overall transmembrane potential

11. **(a)** 0.91 μmol/s • g **(b)** 5.5 s; to provide a constant level of ATP, regulation of ATP production must be tight and rapid.

12. 53 μmol/s • g. With a steady state [ATP] of 7.0 μmol/g, this is equivalent to 10 turnovers of the ATP pool per second; the reservoir would last about 0.13 s.

13. The citric acid cycle is stalled for lack of an acceptor of electrons from NADH. Pyruvate produced by glycolysis cannot enter the cycle as acetyl-CoA; accumulated pyruvate is transaminated to alanine and exported to the liver.

14. Cytosolic malate dehydrogenase plays a key role in the transport of reducing equivalents across the inner mitochondrial membrane via the malate-aspartate shuttle.

15. The inner mitochondrial membrane is impermeable to NADH, but the reducing equivalents of NADH are transferred (shuttled) through the membrane indirectly: they are transferred to oxaloacetate in the cytosol, the resulting malate is transported into the matrix, and mitochondrial NAD^+ is reduced to NADH.

16. Pyruvate dehydrogenase is located in mitochondria; glyceraldehyde 3-phosphate dehydrogenase, in the cytosol. The NAD pools are separated by the inner mitochondrial membrane.

17. **(a)** Glycolysis becomes anaerobic. **(b)** Oxygen consumption ceases. **(c)** Lactate formation increases. **(d)** ATP synthesis decreases to 2 ATP/glucose.

18. The response to **(a)**, increased [ADP], is faster because the response to **(b)**, reduced pO_2, requires protein synthesis.

19. **(a)** NADH is reoxidized via electron transfer instead of lactic acid fermentation. **(b)** Oxidative phosphorylation is more efficient. **(c)** The high mass-action ratio of the ATP system inhibits phosphofructokinase-1.

20. The Pasteur effect is not observed, because the citric acid cycle and respiratory chain are inactive. Fermentation to ethanol could be accomplished in the presence of O_2, which is an advantage because strict anaerobic conditions are difficult to maintain.

21. Reactive oxygen species react with macromolecules, including DNA. If a mitochondrial defect leads to increased production of ROS, proto-oncogenes in the nuclear chromosomes can be damaged, producing oncogenes and leading to unregulated cell division and cancer (see Section 12.9).

22. Different extents of heteroplasmy for the defective gene produce different degrees of defective mitochondrial function.

23. Complete lack of glucokinase (two defective alleles) makes it impossible to carry out glycolysis at a sufficient rate to raise [ATP] to the threshold required for insulin secretion.

24. Defects in Complex II result in increased production of ROS, damage to DNA, and mutations that lead to unregulated cell division (cancer; see Section 12.9). It is not clear why the cancer tends to occur in the midgut.

25. **(a)** Unsaturated fatty acids increase membrane fluidity. **(b)** The cells cannot survive if their membranes contain less than 15% unsaturated fatty acids. **(c)** Oxygen is required for respiration. If cell growth is affected by membrane fluidity only in the presence of oxygen, then logically respiration rates may be affected by membrane fluidity. **(d)** The first observation indicates that something that migrates in the membrane is limiting the rate of respiration. The second observation suggests that respiration is inhibited when unsaturated fatty acid content is low. This might occur if membrane viscosity somehow affected the function of enzymes embedded in the membranes, the passive permeation of oxygen, or the rate of diffusion of a key factor in the membrane itself. **(e)** The overall conclusion is that ubiquinone diffusion through the membrane limits the rate of respiration.

Chapter 20

1. For the maximum photosynthetic rate, PSI (which absorbs light of 700 nm) and PSII (which absorbs light of 680 nm) must be operating simultaneously.

2. From water consumed in the overall reaction

3. H_2S is the hydrogen donor in photosynthesis. No O_2 is evolved, because H_2O is not split; the single photosystem lacks the water-splitting cofactor.

4. **(a)** Stops **(b)** Slows; some electron flow continues by the cyclic pathway.

5. During illumination, a proton gradient is established. When ADP and P_i are added, ATP synthesis is driven by the gradient, which becomes exhausted in the absence of light.

6. DCMU blocks electron transfer between PSII and the first site of ATP production.

7. Venturicidin blocks proton movement through the CF_oCF_1 complex; electron flow (O_2 evolution) continues only until the free-energy cost of pumping protons against the rising proton gradient equals the free energy available in a photon. DNP, by dissipating the proton gradient, restores electron flow and O_2 evolution.

8. From the difference in reduction potentials, you can calculate $\Delta G'^{\circ} = 15$ kJ/mol for the redox reaction. Fig. 20-4 shows that the energy of photons in any region of the visible spectrum is more than sufficient to drive this endergonic reaction. Even photons in the infrared spectrum can provide sufficient energy.

9. 1.35×10^{-77}; the reaction is highly unfavorable! In chloroplasts, the input of light energy overcomes this barrier.

10. –968 kJ/mol

11. No. The electrons from H_2O flow to the artificial electron acceptor Fe^{3+}, not to $NADP^+$.

12. About once every 0.1 s; 1 in 10^8 is excited

13. Light of 700 nm excites PSI, but not PSII; electrons flow from P700 to $NADP^+$, but no electrons flow from P680 to replace them. When light of 680 nm excites PSII, electrons tend to flow to PSI, but the electron carriers between the two photosystems quickly become completely reduced.

14. No. The excited electron from P700 returns to refill the electron "hole" created by illumination. PSII is not needed to supply electrons, and no O_2 is evolved from H_2O. No NADPH is formed, because the excited electron returns to P700. Cyclic photophosphorylation produces ATP rather than NADPH.

15. ATP and NADPH are generated in the light and are essential for CO_2 fixation; conversion stops as the supply of ATP and NADPH becomes exhausted. Some enzymes are switched off in the dark.

16. X is 3-phosphoglycerate; Y is ribulose 1,5-bisphosphate.

17. Ribulose 5-phosphate kinase, fructose 1,6-bisphosphatase, sedoheptulose 1,7-bisphosphatase, and glyceraldehyde 3-phosphate dehydrogenase; all are activated by reduction of a critical disulfide bond to a pair of sulfhydryls, which iodoacetate then blocks irreversibly.

18. The reductive pentose phosphate pathway regenerates ribulose 1,5-bisphosphate from triose phosphates produced during photosynthesis. The oxidative pentose phosphate pathway provides NADPH for reductive biosynthesis and ribose 5-phosphate for nucleotide synthesis.

19. Both types of "respiration" occur in plants, consume O_2, and produce CO_2. (Mitochondrial respiration also occurs in animals.) Mitochondrial respiration takes place continuously, though primarily at night or on cloudy days; electrons derived from various fuels are passed through a chain of carriers in the inner mitochondrial membrane to O_2. Photorespiration takes place in chloroplasts, peroxisomes, and mitochondria, during the daytime, when photosynthetic carbon fixation is occurring. Electron transfer in photorespiration is shown in Fig. 20-43; that for mitochondrial respiration, in Fig. 19-19.

20. In maize, the C_4 pathway fixes CO_2. Phosphoenolpyruvate (PEP) carboxylase carboxylates PEP to form oxaloacetate. Some of the oxaloacetate undergoes transamination to aspartate, but most undergoes reduction to malate in the mesophyll cells. Only after subsequent decarboxylation does the CO_2 enter the Calvin cycle.

21. Measure the amount of $^{14}CO_2$ fixed in leaves during an hour of darkness and an hour of bright illumination. The CAM plant will take up much more CO_2 at night. Alternatively, measure the concentration of organic acids in the vacuoles by titrating an extract of leaves. In darkness, the C_4 plant will have a lower level of titratable acidity.

22. Isocitrate dehydrogenase reaction

23. Rates of photorespiration, which occurs when rubisco uses O_2 rather than CO_2 as a substrate, are increased at higher light intensities and higher leaf temperatures. C_4 plants evolved mechanisms to minimize photorespiration, resulting in an increased ability to perform photosynthesis under these conditions. Because PEP carboxylase has a higher affinity for CO_2 than rubisco, C_4 plants take up more CO_2 under conditions of low $[CO_2]$. Thus, species 1 is a C_4 plant and species 2 is a C_3 plant.

24. $[PP_i]$ is high in the cytosol because the cytosol lacks inorganic pyrophosphatase.

25. (a) Low $[P_i]$ in the cytosol and high [triose phosphate] in the chloroplast **(b)** High $[P_i]$ and [triose phosphate] in the cytosol

26. 3-Phosphoglycerate is the primary product of photosynthesis; $[P_i]$ rises when light-driven synthesis of ATP from ADP and P_i slows.

27. (a) Sucrose + $(\text{glucose})_n \rightarrow (\text{glucose})_{n+1}$ + fructose **(b)** Fructose generated in the synthesis of dextran is readily imported and metabolized by the bacteria.

28. The first enzyme in each path is under reciprocal allosteric regulation. Inhibition of one path shunts isocitrate into the other path.

29. (a) (1) The presence of Mg^{2+} supports the hypothesis that chlorophyll is directly involved in catalysis of the phosphorylation reaction, ADP + $P_i \rightarrow$ ATP. (2) Many enzymes (or other proteins) that contain Mg^{2+} are not phosphorylating enzymes, so the presence of Mg^{2+} in chlorophyll does not prove its role in phosphorylation reactions. (3) The presence of Mg^{2+} is essential to chlorophyll's photochemical properties: light absorption and electron transfer. **(b)** (1) Enzymes catalyze reversible reactions, so an isolated enzyme that can, under certain lab conditions, catalyze removal of a phosphoryl group could probably, under different conditions (such as in cells), catalyze addition of a phosphoryl group. So, chlorophyll could be involved in the phosphorylation of ADP. (2) There are two possible explanations: the chlorophyll protein is a phosphatase only and does not catalyze ADP phosphorylation under cellular conditions, or the crude preparation contains a contaminating phosphatase activity that is unconnected to the photosynthetic reactions. (3) The preparation was probably contaminated with a nonphotosynthetic phosphatase activity. **(c)** (1) This light inhibition would be expected if the chlorophyll protein catalyzed the reaction ADP + P_i + light $\rightarrow$ ATP. Without light, the reverse reaction, a dephosphorylation, would be favored. In the presence of light, energy is provided and the equilibrium would shift to the right, reducing the phosphatase activity. (2) This inhibition must be an artifact of the isolation or assay methods. (3) The crude preparation methods in use at the time were unlikely to preserve intact chloroplast membranes, so the inhibition must be an artifact. **(d)** In the presence of light, (1) ATP is synthesized and other phosphorylated intermediates are consumed; (2) glucose is produced and is metabolized by cellular respiration to produce ATP, with changes in the levels of phosphorylated intermediates; (3) ATP is produced and other phosphorylated intermediates are consumed. **(e)** Light energy is used to produce ATP (as in the Emerson model) *and* is used to produce reducing power (as in the Rabinowitch model). **(f)** The approximate stoichiometry for photophosphorylation is that 8 photons yield 2 NADPH and about 3 ATP. To reduce 1 CO_2 requires 2 NADPH and 3 ATP. Thus, at a minimum, 8 photons are required per CO_2 molecule reduced, in good agreement with Rabinowitch's value. **(g)** Because the energy of light is used to produce *both* ATP and NADPH, each photon absorbed contributes more than just 1 ATP for photosynthesis. The process of energy extraction from light is more efficient than Rabinowitch supposed, and plenty of energy is available for this process—even with red light.

Chapter 21

1. (a) The 16 carbons of palmitate are derived from 8 acetyl groups of 8 acetyl-CoA molecules. The ^{14}C-labeled acetyl-CoA gives rise to malonyl-CoA labeled at C-1 and C-2. **(b)** The metabolic pool of malonyl-CoA, the source of all palmitate carbons except C-16 and C-15, does not become labeled with small amounts of ^{14}C-labeled acetyl-CoA. Hence, only $[15,16\text{-}^{14}C]$ palmitate is formed.

2. Both glucose and fructose are degraded to pyruvate in glycolysis. Pyruvate is converted to acetyl-CoA by the pyruvate dehydrogenase complex. Some of this acetyl-CoA enters the citric acid cycle, which produces reducing equivalents, NADH and NADPH. Mitochondrial electron transfer to O_2 yields ATP.

3. $$8\ \text{Acetyl-CoA} + 15\text{ATP} + 14\text{NADPH} + 9H_2O \rightarrow \text{palmitate} + 8\text{CoA} + 15\text{ADP} + 15P_i + 14\text{NADP}^+ + 2H^+$$

4. (a) 3 deuteriums per palmitate; all located on C-16; all other two-carbon units are derived from unlabeled malonyl-CoA **(b)** 7 deuteriums per palmitate; located on all *even*-numbered carbons except C-16

5. By using the three-carbon unit malonyl-CoA, the activated form of acetyl-CoA (recall that malonyl-CoA synthesis requires ATP), metabolism is driven in the direction of fatty acid synthesis by the exergonic release of CO_2.

6. (a) The rate-limiting step in fatty acid synthesis is carboxylation of acetyl-CoA, catalyzed by acetyl-CoA carboxylase. High [citrate] and [isocitrate] indicate that conditions are favorable for fatty acid synthesis: an active citric acid cycle is providing a plentiful supply of ATP, reduced pyridine nucleotides, and acetyl-CoA. Citrate stimulates (increases the V_{max} of) acetyl-CoA carboxylase **(b)**. Because citrate binds more tightly to the filamentous (active) form of the enzyme, high [citrate] drives the protomer $\rightleftharpoons$ filament equilibrium in the direction of the active form. In contrast, palmitoyl-CoA (the end product of fatty acid synthesis) drives the equilibrium in the direction of the inactive (protomer) form. Hence, when the end product of fatty acid synthesis accumulates, the biosynthetic path slows.

7. (a) $\text{Acetyl-CoA}_{(mit)} + \text{ATP} + \text{CoA}_{(cyt)} \rightarrow$

$$\text{acetyl-CoA}_{(cyt)} + \text{ADP} + \text{P}_i + \text{CoA}_{(mit)}$$

(b) 1 ATP per acetyl group **(c)** Yes

8. No. The double bond in palmitoleate is introduced by an oxidation catalyzed by fatty acyl–CoA desaturase, a mixed-function oxidase that requires O_2 as a cosubstrate.

9. $3\ \text{Palmitate} + \text{glycerol} + 7\text{ATP} + 4H_2O \rightarrow$

$$\text{tripalmitin} + 7\text{ADP} + 7\text{P}_i + 7\text{H}^+$$

10. In adult rats, stored triacylglycerols are maintained at a steady-state level through a balance of rates of degradation and biosynthesis. Hence, triacylglycerols of adipose (fat) tissue are constantly turned over, which explains the incorporation of ^{14}C label from dietary glucose.

11. Net reaction:

$\text{Dihydroxyacetone phosphate} + \text{NADH} + \text{palmitate} + \text{oleate} + 3\text{ATP} + \text{CTP} + \text{choline} + 4H_2O \rightarrow$

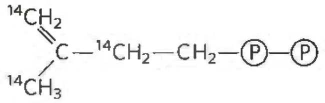
$$\text{phosphatidylcholine} + \text{NAD}^+ + 2\text{AMP} + \text{ADP} + \text{H}^+ + \text{CMP} + 5\text{P}_i$$

7ATP per molecule of phosphatidylcholine

12. Methionine deficiency reduces the level of adoMet, which is required for de novo synthesis of phosphatidylcholine. The salvage pathway does not employ adoMet, but uses available choline. Thus phosphatidylcholine can be synthesized even when the diet is deficient in methionine, as long as choline is available.

13. During cholesterol biosynthesis, the two Claisen condensations involving acetyl-CoA and leading to HMG-CoA are both thermodynamically unfavorable. However, the product HMG-CoA is rapidly siphoned off by more thermodynamically favorable subsequent reactions. In fatty acid synthesis, all of the condensation reactions involving each new malonyl-CoA are identical. If acetyl-CoA were utilized instead of malonyl-CoA, all would be thermodynamically unfavorable. As subsequent reduction steps that expend NADPH in each four-step cycle are also thermodynamically unfavorable, there are no downstream processes capable of balancing the thermodynamics and pulling the sequence toward synthesis. The synthesis of long fatty acids would not be chemically feasible without the use of malonyl-CoA and the thermodynamic boost provided by decarboxylation.

14. ^{14}C label appears in three places in the activated isoprene:



15. (a) ATP **(b)** UDP-glucose **(c)** CDP-ethanolamine **(d)** UDP-galactose **(e)** Fatty acyl–CoA **(f)** *S*-Adenosylmethionine **(g)** Malonyl-CoA **(h)** Δ^3-Isopentenyl pyrophosphate

16. Linoleate is required in the synthesis of prostaglandins. Animals cannot transform oleate to linoleate, so linoleate is an essential fatty acid. Plants can convert oleate to linoleate, and they provide animals with the required linoleate (see Fig. 21-12).

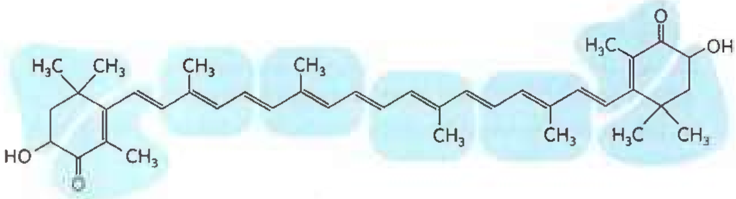
17. The rate-determining step in the biosynthesis of cholesterol is the synthesis of mevalonate, catalyzed by HMG-CoA reductase. This enzyme is allosterically regulated by mevalonate and cholesterol derivatives. High intracellular [cholesterol] also reduces transcription of the gene encoding HMG-CoA reductase.

18. When cholesterol levels decline because of treatment with a statin, cells attempt to compensate by increasing expression of the gene encoding HMG-CoA reductase; however, statins are good competitive inhibitors of HMG-CoA reductase activity and reduce overall production of cholesterol.

19. Note: In the absence of detailed knowledge of the literature on this enzyme, students might propose several plausible alternatives. *Thiolase reaction:* Begins with nucleophilic attack of an active-site Cys residue on the first acetyl-CoA substrate, displacing —S-CoA and forming a covalent thioester link between Cys and the acetyl group. A base on the enzyme then extracts a proton from the methyl group of the second acetyl-CoA, leaving a carbanion that attacks the carbonyl carbon of the thioester formed in the first step. The sulfhydryl of the Cys residue is displaced, creating the product acetoacetyl-CoA. *HMG-CoA synthase reaction:* Begins in the same way, with a covalent thioester link formed between the enzyme's Cys residue and the acetyl group of acetyl-CoA, with displacement of —S-CoA. The —S-CoA dissociates as CoA-SH, and acetoacetyl-CoA binds to the enzyme. A proton is abstracted from the methyl group of the enzyme-linked acetyl, forming a carbanion that attacks the ketone carbonyl of the acetoacetyl-CoA substrate. The carbonyl is converted to a hydroxyl ion in this reaction, which is protonated to create —OH. The thioester link with the enzyme is then cleaved hydrolytically to generate the HMG-CoA product. *HMG-CoA reductase reaction:* Two successive hydride ions derived from NADPH first displace the —S-CoA, and then reduce the aldehyde to a hydroxyl group.

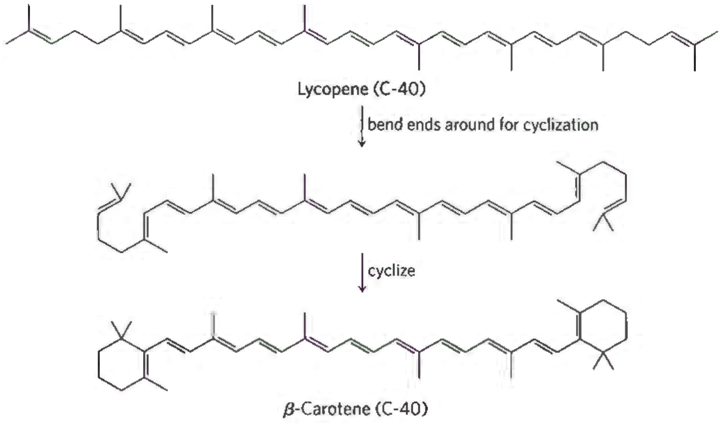
20. Statins inhibit HMG-CoA reductase, an enzyme in the pathway to the synthesis of activated isoprenes, which are precursors of cholesterol and a wide range of isoprenoids, including coenzyme Q (ubiquinone). Hence, statins might reduce the levels of coenzyme Q available for mitochondrial respiration. Ubiquinone is obtained in the diet as well as by direct biosynthesis, but it is not yet clear how much is required and how well dietary sources can substitute for reduced synthesis. Reductions in the levels of particular isoprenoids may account for some side effects of statins.

21. (a)



Astaxanthin

(b) Head-to-head. There are two ways to look at this. First, the "tail" of geranylgeranyl pyrophosphate has a branched dimethyl structure, as do both ends of phytoene. Second, no free —OH is formed by the release of PP_i, indicating that the two —O—Ⓟ—Ⓟ "heads" are linked to form phytoene. **(c)** Four rounds of dehydrogenation convert four single bonds to double bonds. **(d)** No. A count of single and double bonds in the reaction below shows that one double bond is replaced by two single bonds—so, there is no net oxidation or reduction:



(e) Steps ❶ through ❸. The enzyme can convert IPP and DMAP to geranylgeranyl pyrophosphate, but it catalyzes no further reactions in the pathway, as confirmed by results with the other substrates. **(f)** Strains 1 through 4 lack *crtE* and have much lower astaxanthin production than strains 5 through 8, all of which overexpress *crtE*. Thus, overexpression of *crtE* leads to a substantial increase in astaxanthin production. Wild-type *E. coli* has some step ❸ activity, but this conversion of farnesyl pyrophosphate to geranylgeranyl pyrophosphate is strongly rate-limiting. **(g)** IPP isomerase. Comparing strains 5 and 6 shows that adding *ispA*, which catalyzes steps ❶ and ❷, has little effect on astaxanthin production, so these steps are not rate-limiting. However, comparing strains 5 and 7 shows that adding *idi* substantially increases astaxanthin production, so IPP isomerase must be the rate-limiting step when *crtE* is overexpressed.

Chapter 22

1. In their symbiotic relationship with the plant, bacteria supply ammonium ion by reducing atmospheric nitrogen, a process that requires large quantities of ATP because of the very high activation energy of ammonia production from N_2.

2. Fixed nitrogen is limiting in most environments, including marine ecosystems. Large increases in fixed nitrogen help to feed algae blooms, with an accompanying increase in aerobic respiration, which depletes oxygen in the affected waters.

3. A link is formed between enzyme-bound PLP and the phosphohomoserine substrate, with rearrangement to generate the ketimine at the α carbon of the substrate. This activates the β carbon for proton abstraction, leading to displacement of the phosphate and formation of a double bond between the β and γ carbons. A rearrangement (beginning with proton abstraction at the pyridoxal carbon adjacent to the substrate amino nitrogen) moves the α–β double bond and converts the ketimine to the aldimine form of PLP. Attack of water at the β carbon is then facilitated by the linked pyridoxal, followed by hydrolysis of the imine link between PLP and the product, to generate threonine.

4. In the mammalian route, toxic ammonium ions are transformed to glutamine, reducing toxic effects on the brain.

5. Glucose + $2CO_2$ + $2NH_3$ → 2 aspartate + $2H^+$ + $2H_2O$

6. The amino-terminal glutaminase domain is similar in *all* glutamine amidotransferases. A drug that targeted this active site would probably inhibit many enzymes and produce many more side effects than a more specific inhibitor that targets the unique carboxyl-terminal synthetase active site.

7. If phenylalanine hydroxylase is defective, the biosynthetic route to tyrosine is blocked and tyrosine must be obtained from the diet.

8. The biosynthetic pathway requires reduction of the γ-carboxyl group of glutamate to a carbonyl. Prior acetylation of the α-amino group prevents a spontaneous cyclization reaction that leads not to arginine, but to proline.

9. In adoMet synthesis, triphosphate is released from ATP. Hydrolysis of the triphosphate renders the reaction thermodynamically more favorable.

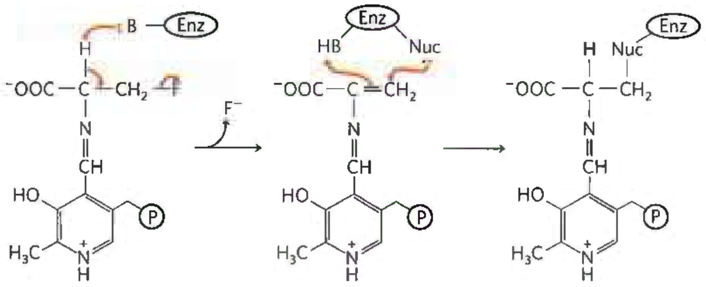
10. If the inhibition of glutamine synthase were not concerted, saturating concentrations of histidine would shut down the enzyme and cut off production of glutamine, which the bacterium needs to synthesize other products.

11. Folic acid is a precursor of tetrahydrofolate (see Fig. 18-16), required in the biosynthesis of glycine (see Fig. 22-14), a precursor of porphyrins. A folic acid deficiency therefore impairs hemoglobin synthesis.

12. This is a PLP-catalyzed decarboxylation.

13. *Glycine auxotrophs:* adenine and guanine; *glutamine auxotrophs:* adenine, guanine, and cytosine; *aspartate auxotrophs:* adenine, guanine, cytosine, and uridine

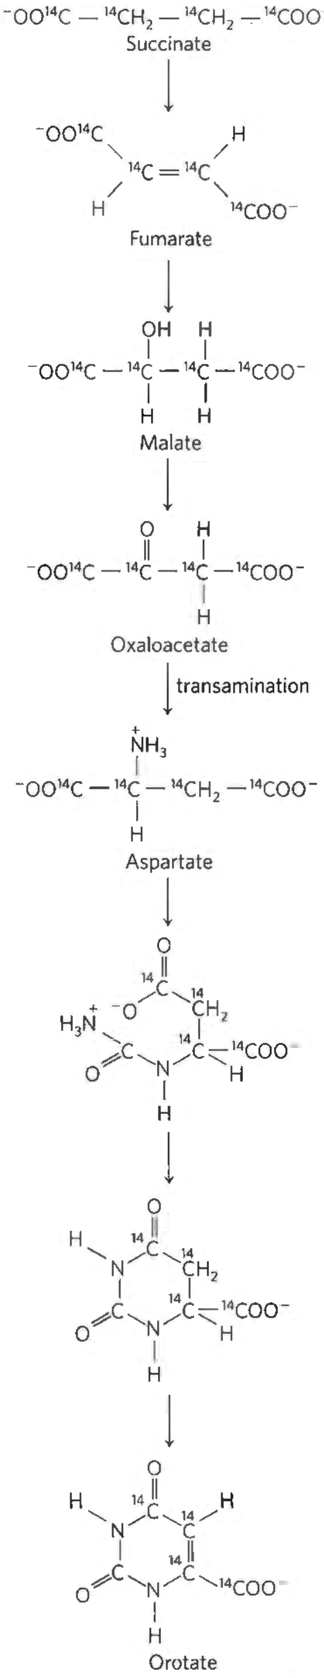
14. See Fig. 18-6, step ❷, for the reaction mechanism of amino acid racemization. The F atom of fluoroalanine is an excellent leaving group. Fluoroalanine causes irreversible (covalent) inhibition of alanine racemase. One plausible mechanism (where Nuc denotes any nucleophilic amino acid side chain in the enzyme active site) is



15. (a) As shown in Fig. 18-16, *p*-aminobenzoate is a component of tetrahydrofolate (H_4 folate), the cofactor involved in the transfer of one-carbon units. **(b)** In the presence of sulfanilamide, a structural analog of *p*-aminobenzoate, bacteria are unable to synthesize tetrahydrofolate, a cofactor necessary for converting AICAR to FAICAR; thus, AICAR accumulates. **(c)** The competitive inhibition by sulfanilamide of the enzyme involved in tetrahydrofolate biosynthesis is overcome by the addition of excess substrate (*p*-aminobenzoate).

16. (b) and **(d)**

17. The ^{14}C-labeled orotate arises from the following pathway (the first three steps are part of the citric acid cycle):

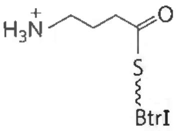


18. Organisms do not store nucleotides to be used as fuel, and they do not completely degrade them, but rather hydrolyze them to release the bases, which can be recovered in salvage pathways. The low C:N ratio of nucleotides makes them poor sources of energy.

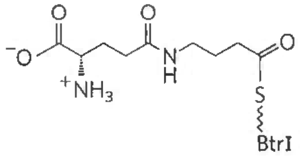
19. Treatment with allopurinol has two consequences. (1) It inhibits conversion of hypoxanthine to uric acid, causing accumulation of hypoxanthine, which is more soluble and more readily excreted; this alleviates the clinical problems associated with AMP degradation. (2) It inhibits conversion of guanine to uric acid, causing accumulation of xanthine, which is less soluble than uric acid; this is the source of xanthine stones. Because the amount of GMP degradation is low relative to AMP degradation, the kidney damage caused by xanthine stones is less than the damage caused by untreated gout.

20. Tetrahydrofolate is utilized in thymidylate synthesis, and also in the synthesis of glycine from serine.

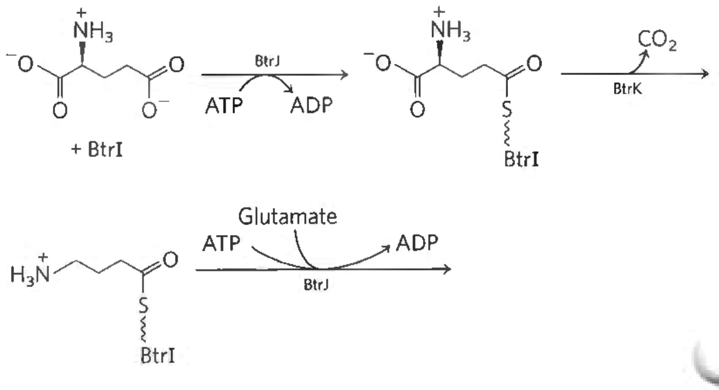
21. (a) The α-carboxyl group is removed and an —OH is added to the γ carbon. **(b)** BtrI has sequence homology with acyl carrier proteins. The molecular weight of BtrI increases when incubated under conditions in which CoA could be added to the protein. Adding CoA to a Ser residue would replace an —OH, formula weight (FW) 17, with a 4′-phosphopantetheine group (see Fig. 21-5; formula $C_{11}H_{21}N_2O_7PS$), FW 356. Thus, $11{,}182 - 17 + 356 = 12{,}151$, which is very close to the observed M_r of 12,153. **(c)** The thioester could form with the α-carboxyl group. **(d)** In the most common reaction for removing the α-carboxyl group of an amino acid (see Fig. 18-6, reaction Ⓒ), the carboxyl group must be free. Furthermore, it is difficult to imagine a decarboxylation reaction starting with a carboxyl group in its thioester form. **(e)** $12{,}240 - 12{,}281 = 41$, close to the M_r of CO_2 (44). Given that BtrK is probably a decarboxylase, the most likely structure is the decarboxylated form:

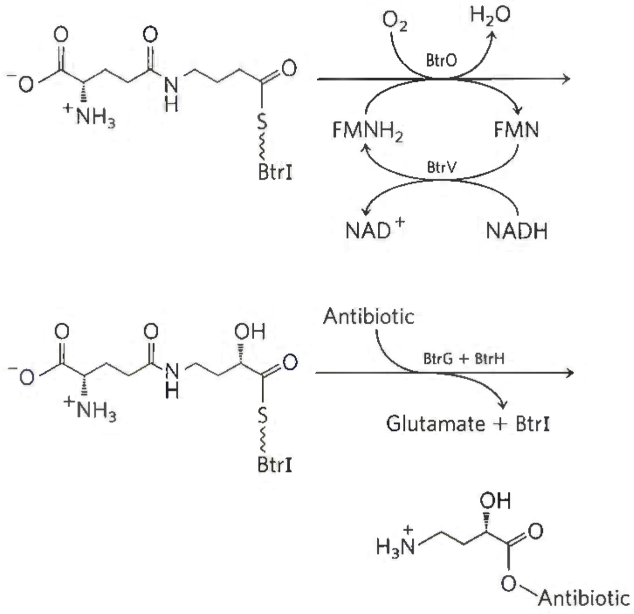


(f) $12{,}370 - 12{,}240 = 130$. Glutamic acid ($C_5H_9NO_4$; M_r 147), minus the —OH (FW 17) removed in the glutamylation reaction, leaves a glutamyl group of FW 130; thus, γ-glutamylating the molecule shown above would add 130 to its M_r. BtrJ is capable of γ-glutamylating other substrates, so it may γ-glutamylate this molecule. The most likely site for this is the free amino group, giving the following structure:



(g)





Chapter 23

1. They are recognized by two different receptors, typically found in different cell types, and are coupled to different downstream effectors.

2. Ammonia is highly toxic to nervous tissue, especially the brain. In healthy individuals, excess NH_3 is removed by transformation of glutamate to glutamine, which travels to the liver and is subsequently transformed to urea. The additional glutamine arises from conversion of glucose to α-ketoglutarate, transamination of α-ketoglutarate to glutamate, and conversion of glutamate to glutamine.

3. Glucogenic amino acids are used to make glucose for the brain; others are deaminated, then oxidized in mitochondria via the citric acid cycle.

4. From glucose, by the following route: Glucose → dihydroxyacetone phosphate (in glycolysis); dihydroxyacetone phosphate + NADH + H^+ → glycerol 3-phosphate + NAD^+ (glycerol 3-phosphate dehydrogenase reaction)

5. **(a)** Increased muscular activity increases the demand for ATP, which is met by increased O_2 consumption. **(b)** After the sprint, lactate produced by anaerobic glycolysis is converted to glucose and glycogen, which requires ATP and therefore O_2.

6. Glucose is the primary fuel for the brain. TPP-dependent oxidative decarboxylation of pyruvate to acetyl-CoA is essential to complete glucose metabolism. TPP synthesis requires the vitamin thiamine.

7. 5.5×10^7 L. For comparison, an Olympic pool, 50 m long, 25 m wide, and 2 m deep, holds 2.5×10^6 L.

8. **(a)** Inactivation provides a rapid means to change the concentration of active hormone and thus end its effects. **(b)** Changes in the rate of release from storage, the rate of conversion from prohormone to active hormone, and the rate of inactivation can rapidly change the level of a circulating peptide hormone.

9. Water-soluble hormones bind to receptors on the outer surface of the cell, triggering formation of a second messenger (e.g., cAMP) inside the cell. Lipid-soluble hormones can pass through the plasma membrane to act on target molecules or receptors directly.

10. **(a)** Skeletal muscle does not express glucose 6-phosphatase. Any glucose 6-phosphate produced enters the glycolytic pathway and, under O_2-deficient conditions, is converted to lactate via pyruvate. **(b)** In a "fight-or-flight" situation, the concentration of glycolytic precursors must be high in preparation for muscular activity. Phosphorylated intermediates cannot escape from myocytes because the membrane is not permeable to charged species, and glucose 6-phosphate is not exported by the glucose transporter. In the liver, glucose is formed from glucose 6-phosphate and enters the bloodstream to maintain the blood glucose level in the homeostatic range.

11. **(a)** Excessive uptake and use of blood glucose by the liver, leading to hypoglycemia; shutdown of amino acid and fatty acid catabolism **(b)** Little circulating fuel is available for ATP requirements. Brain damage results because glucose is the main source of fuel for the brain.

12. As an uncoupler of oxidative phosphorylation, thyroxine would decrease the efficiency of the process (lower the P/O ratio), forcing the tissue to increase respiration to meet the normal demand for ATP. This less-efficient respiration would dissipate as heat a greater proportion of the energy potentially available for making ATP. Thermogenesis could also be due to the increased rate of ATP use by the thyroid-stimulated tissue. In this case, the efficiency of oxidative phosphorylation (the P/O ratio) would be unchanged. But because some energy is always dissipated as heat in the process, the increased production of ATP demanded by the stimulated tissue would produce more heat overall.

13. Because prohormones are inactive, they can be stored in quantity in secretory granules. Rapid activation is achieved by enzymatic cleavage in response to an appropriate signal.

14. In animals, glucose can be synthesized from many precursors (see Fig. 14-15). In humans, the principal precursors are glycerol from TAGs, glucogenic amino acids from protein degradation, and oxaloacetate formed by pyruvate carboxylase.

15. The *ob/ob* mouse, which is initially obese, will lose weight. The *OB/OB* mouse will retain its normal body weight.

16. BMI = 39.3. For a BMI of 25, weight must be 75 kg; he must lose 43 kg, or 95 lb.

17. Reduced insulin secretion. Valinomycin has the same effect as opening the K^+ channel, allowing K^+ exit and consequent hyperpolarization.

18. The liver does not receive the insulin message and therefore continues to have high levels of glucose 6-phosphatase and gluconeogenesis, increasing blood glucose both during a fast and after a glucose-containing meal. The elevated blood glucose triggers insulin release from pancreatic β cells, hence the high level of insulin in the blood.

19. Some things to consider: What do the data show about the frequency of heart attack attributable to the drug among people taking the drug? How does this frequency compare with the data on individuals spared the long-term consequences of type 2 diabetes? Are other, equally effective treatment options with fewer adverse effects available?

20. Without intestinal glucosidase activity, absorption of glucose from dietary glycogen and starch is reduced, blunting the usual rise in blood glucose after a meal. The undigested oligosaccharides are fermented by intestinal bacteria, and the gases released cause intestinal discomfort.

21. **(a)** Increased; closing the ATP-gated K^+ channel would depolarize the membrane, increasing insulin release. **(b)** Type 2 diabetes results from decreased sensitivity to insulin, not a deficit of insulin production; increasing circulating insulin levels will reduce the symptoms associated with this disease. **(c)** Individuals with type 1 diabetes have deficient pancreatic β cells, so glyburide will have no beneficial effect. **(d)** Iodine, like chlorine (the atom it replaces in the labeled glyburide), is a halogen, but it is a larger atom and has slightly different chemical properties. The iodinated glyburide might not bind to SUR. If it bound to another molecule instead, the experiment would result in cloning of the gene for this other, incorrect protein. **(e)** Although a protein has been "purified," the "purified" preparation might be a mixture of several proteins that co-purify under those experimental conditions. In this case, the amino acid sequence could be that of a protein that co-purifies with SUR. Using antibody binding to show that the peptide sequences are present in SUR excludes this possibility. **(f)** Although the cloned gene does encode the 25 amino acid sequence found in SUR, it could be a gene that, coincidentally, encodes the same sequence in another protein. In this case, this other gene would most likely be expressed in different cells than the *SUR* gene. The mRNA hybridization results are consistent with the putative *SUR* cDNA actually encoding SUR. **(g)** The excess unlabeled glyburide competes with labeled glyburide for the binding site on SUR. As a result, there is significantly less binding of labeled glyburide, so little or no radioactivity is detected in the 140 kDa protein. **(h)** In the absence of excess unlabeled glyburide, labeled 140 kDa protein is found only in the presence of the putative *SUR* cDNA. Excess unlabeled glyburide competes with the labeled glyburide, and no ^{125}I-labeled 140 kDa protein is detected. This shows that the cDNA produces a glyburide-binding protein of the same molecular weight as SUR—strong evidence that the cloned gene encodes the SUR protein. **(i)** Several additional steps are possible, such as the following: (1) Express the putative *SUR* cDNA in CHO (Chinese hamster ovary) cells and show that the transformed cells have ATP-gated K^+ channel activity. (2) Show that HIT cells with mutations in the putative *SUR* gene lack ATP-gated K^+ channel activity. (3) Show that humans or experimental animals with mutations in the putative *SUR* gene are unable to secrete insulin.

Chapter 24

1. 6.1×10^4 nm; 290 times longer than the T2 phage head

2. The number of A residues does not equal the number of T residues, nor does the number of G equal the number of C, so the DNA is not a base-paired double helix; the M13 DNA is single-stranded.

3. $M_r = 3.8 \times 10^8$; length = 200 μm; $Lk_0 = 55{,}200$; $Lk = 51{,}900$

4. The exons contain 3 bp/amino acid × 192 amino acids = 576 bp. The remaining 864 bp are in introns, possibly in a leader or signal sequence, and/or in other noncoding DNA.

5. 5,000 bp. **(a)** Doesn't change; *Lk* cannot change without breaking and re-forming the covalent backbone of the DNA. **(b)** Becomes undefined; a circular DNA with a break in one strand has, by definition, no *Lk*. **(c)** Decreases; in the presence of ATP, gyrase underwinds DNA. **(d)** Doesn't change; this assumes that neither of the DNA strands is broken in the heating process.

6. For *Lk* to remain unchanged, the topoisomerase must introduce the same number of positive and negative supercoils.

7. $\sigma = -0.067$; >70% probability

8. (a) Undefined; the strands of a nicked DNA could be separated and thus have no *Lk*. **(b)** 476 **(c)** The DNA is already relaxed, so the topoisomerase does not cause a net change; *Lk* = 476. **(d)** 460; gyrase plus ATP reduces the *Lk* in increments of 2. **(e)** 464; eukaryotic type I topoisomerases increase the *Lk* of underwound or negatively supercoiled DNA in increments of 1. **(f)** 460; nucleosome binding does not break any DNA strands and thus cannot change *Lk*.

9. A fundamental structural unit in chromatin repeats about every 200 bp; the DNA is accessible to the nuclease only at 200 bp intervals. The brief treatment was insufficient to cleave the DNA at every accessible point, so a ladder of DNA bands is created in which the DNA fragments are multiples of 200 bp. The thickness of the DNA bands suggests that the distance between cleavage sites varies somewhat. For instance, not all the fragments in the lowest band are exactly 200 bp long.

10. A right-handed helix has a positive *Lk*; a left-handed helix (such as Z-DNA) has a negative *Lk*. Decreasing the *Lk* of a closed circular B-DNA by underwinding facilitates formation of regions of Z-DNA within certain sequences. (See Chapter 8, p. 273, for a description of sequences that permit the formation of Z-DNA.)

11. (a) Both strands must be covalently closed, and the molecule must be either circular or constrained at both ends. **(b)** Formation of cruciforms, left-handed Z-DNA, plectonemic or solenoidal supercoils, and unwinding of the DNA are favored. **(c)** *E. coli* DNA topoisomerase II or DNA gyrase **(d)** It binds the DNA at a point where it crosses on itself, cleaves both strands of one of the crossing segments, passes the other segment through the break, then reseals the break. The result is a change in *Lk* of –2.

12. Centromere, telomeres, and an autonomous replicating sequence or replication origin

13. The bacterial nucleoid is organized into domains approximately 10,000 bp long. Cleavage by a restriction enzyme relaxes the DNA within a domain, but not outside the domain. Any gene in the cleaved domain for which expression is affected by DNA topology will be affected by the cleavage; genes outside the domain will not.

14. (a) The lower, faster-migrating band is negatively supercoiled plasmid DNA. The upper band is nicked, relaxed DNA. **(b)** DNA topoisomerase I would relax the supercoiled DNA. The lower band would disappear, and all of the DNA would converge on the upper band. **(c)** DNA ligase would produce little change in the pattern. Some minor additional bands might appear near the upper band, due to the trapping of topoisomers not quite perfectly relaxed by the ligation reaction. **(d)** The upper band would disappear, and all of the DNA would be in the lower band. The supercoiled DNA in the lower band might become even more supercoiled and migrate somewhat faster.

15. (a) When DNA ends are sealed to create a relaxed, closed circle, some DNA species are completely relaxed but others are trapped in slightly underwound or overwound states. This gives rise to a distribution of topoisomers centered on the most relaxed species. **(b)** Positively supercoiled **(c)** The DNA that is relaxed despite the addition of dye is DNA with one or both strands broken. DNA isolation procedures inevitably introduce small numbers of strand breaks in some of the closed-circular molecules. **(d)** –0.05. This is determined by simply comparing native DNA with samples of known σ. In both gels, the native DNA migrates most closely with the sample of $\sigma = -0.049$.

16. 62 million (the genome refers to the haploid genetic content of the cell; the cell is actually diploid, so the number of nucleosomes is doubled). The number is obtained by dividing 3.1 billion bp by 200 bp/nucleosome (giving 15.5 million nucleosomes), multiplying by 2 copies of H2A per nucleosome, and again multiplying by 2 to account for the diploid state of the cell. The 62 million would double upon replication.

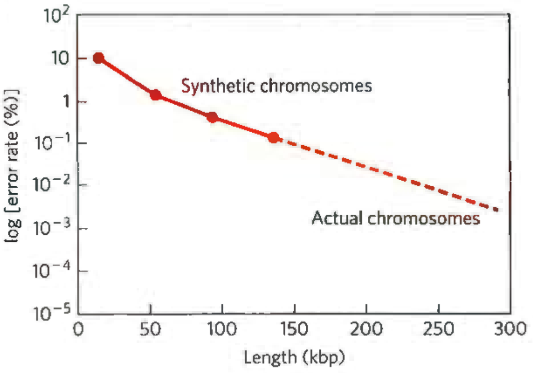
17. DNA topoisomerase IV is needed to decatenate the two circular chromosome products of DNA replication prior to cell division.

18. A TAD, or topologically associating domain, is a DNA loop that is bound and constrained at its base. Supercoiling within the TAD is maintained in part by the restriction to free DNA rotation imposed by the protein binding at the base of the loop.

19. (a) In nondisjunction, one daughter cell and all of its descendants get two copies of the synthetic chromosome and are white; the other daughter cell and all of its descendants get no copies of the synthetic chromosome and are red. This gives rise to a half-white, half-red colony. **(b)** In chromosome loss, one daughter cell and all of its descendants get one copy of the synthetic chromosome and are pink; the other daughter cell and all of its descendants get no copies of the synthetic chromosome and are red. This gives rise to a half-pink, half-red colony. **(c)** The minimum functional centromere must be smaller than 0.63 kbp, because all fragments of this size or larger confer relative mitotic stability. **(d)** Telomeres are required to fully replicate only linear DNA; a circular molecule can replicate without them.

(e) The larger the chromosome, the more faithfully it is segregated. The data show neither a minimum size below which the synthetic chromosome is completely unstable nor a maximum size above which stability no longer changes.

(f)

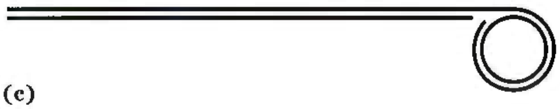


As shown in the graph, even if the synthetic chromosomes were as long as the normal yeast chromosomes, they would not be as stable. This suggests that other, as yet undiscovered, elements are required for stability.

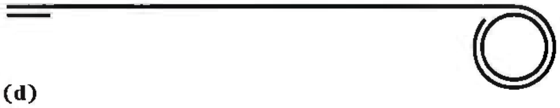
Chapter 25

1. (a) Structure **1**

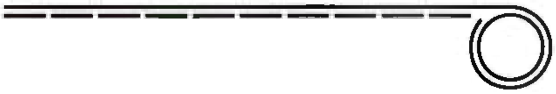
(b)



(c)



(d)



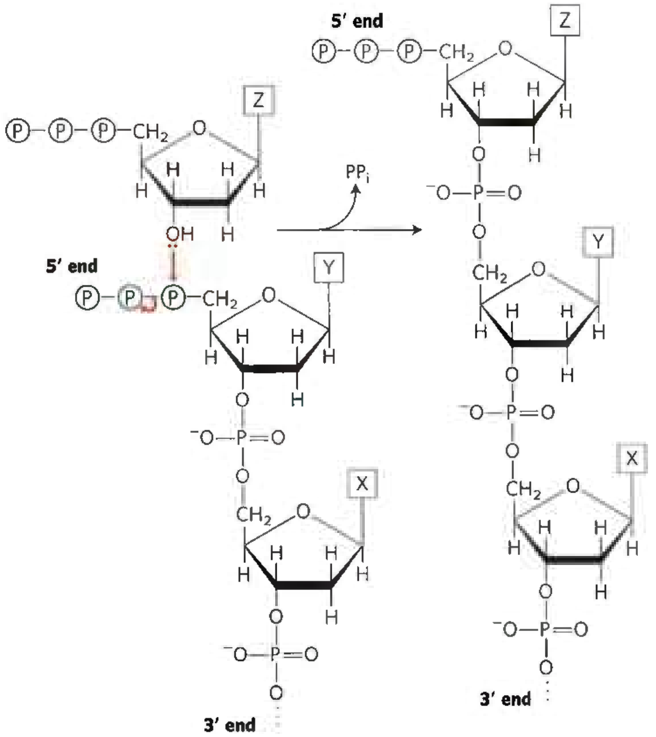
2. This is an extension of the classic Meselson-Stahl experiment. After three generations the molar ratio of ^{15}N–^{14}N DNA to ^{14}N–^{14}N DNA is 2/6 = 0.33.

3. (a) 4.42×10^5 turns **(b)** 40 min. In cells dividing every 20 min, a replicative cycle is initiated every 20 min, each cycle beginning before the prior one is complete. **(c)** 2,000 to 5,000 Okazaki fragments. The fragments are 1,000 to 2,000 nucleotides long. The ligation of Okazaki fragments does not occur randomly. Each fragment is stably base-paired with the lagging strand template prior to ligation with its neighbor, ensuring proper ordering.

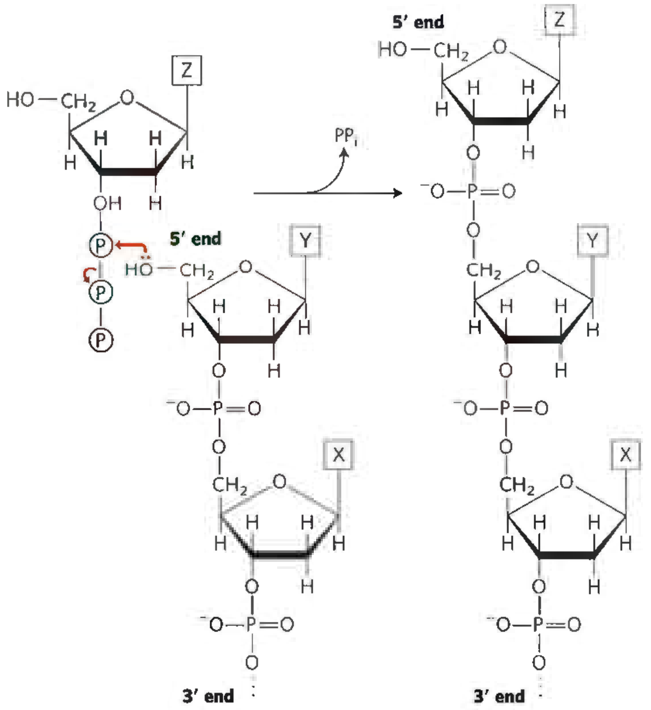
4. A, 28.7%; G, 21.3%; C, 21.3%; T, 28.7%. The DNA strand made from the template strand: A, 32.7%; G, 18.5%; C, 24.1%; T, 24.7%; the DNA strand made from the complementary template strand: A, 24.7%; G, 24.1%; C, 18.5%; T, 32.7%. This assumes that the two template strands are replicated completely.

5. (a) No. Incorporation of ^{32}P into DNA results from the synthesis of new DNA, which requires the presence of *all four* nucleotide precursors. **(b)** Yes. Although all four nucleotide precursors must be present for DNA synthesis, only one of them has to be radioactive for radioactivity to appear in the new DNA. **(c)** No. Radioactivity is incorporated only if the ^{32}P label is in the α phosphate; DNA polymerase cleaves off pyrophosphate—that is, the β- and γ-phosphate groups.

6. *Mechanism 1:* 3′-OH group of an incoming dNTP attacks the α phosphate of the triphosphate at the 5′ end of the growing DNA strand, displacing pyrophosphate. This mechanism uses normal dNTPs, and the growing end of the DNA always has a triphosphate on the 5′ end.



Mechanism 2: This uses a new type of precursor, nucleotide 3′-triphosphates. The growing end of the DNA strand has a 5′-OH group, which attacks the α phosphate of an incoming deoxynucleoside 3′-triphosphate, displacing pyrophosphate. Note that this mechanism would require the evolution of new metabolic pathways to supply the needed deoxynucleoside 3′-triphosphates.



7. The DNA polymerase contains a 3′→5′ exonuclease activity that degrades DNA to produce [^{32}P]dNMPs. The activity is not a 5′→3′

exonuclease, because the addition of unlabeled dNTPs inhibits the production of [^{32}P]dNMPs (polymerization activity would suppress a proofreading exonuclease but not an exonuclease operating downstream of the polymerase). Addition of pyrophosphate would generate [^{32}P]dNTPs through reversal of the polymerase reaction.

8. *Leading strand:* Precursors: dATP, dGTP, dCTP, dTTP (also needs a template DNA strand and DNA primer); enzymes and other proteins: DNA gyrase, helicase, single-stranded DNA–binding protein, DNA polymerase III, topoisomerases, and pyrophosphatase. *Lagging strand:* Precursors: ATP, GTP, CTP, UTP, dATP, dGTP, dCTP, dTTP (also needs an RNA primer); enzymes and other proteins: DNA gyrase, helicase, single-stranded DNA–binding protein, primase, DNA polymerase III, DNA polymerase I, DNA ligase, topoisomerases, and pyrophosphatase. NAD$^+$ is also required as a cofactor for DNA ligase.

9. Mutants with defective DNA ligase produce a DNA duplex in which one of the strands remains in pieces (as Okazaki fragments). When this duplex is denatured, sedimentation results in one fraction containing the intact single strand (the high molecular weight band) and one fraction containing the unspliced fragments (the low molecular weight band).

10. Watson-Crick base pairing between template and leading strand; proofreading and removal of wrongly inserted nucleotides by the 3′-exonuclease activity of DNA polymerase III. Yes—perhaps. Because the factors ensuring fidelity of replication are operative in both the leading and the lagging strands, the lagging strand would probably be made with the same fidelity. However, the greater number of distinct chemical operations involved in making the lagging strand might provide a greater opportunity for errors to arise.

11. ~1,200 bp (600 in each direction)

12. A small fraction (13 of 10^9 cells) of the histidine-requiring mutants spontaneously undergo back-mutation and regain their capacity to synthesize histidine. 2-Aminoanthracene increases the rate of back-mutations about 1,800-fold and is therefore mutagenic. Since most carcinogens are mutagenic, 2-aminoanthracene is probably carcinogenic.

13. Spontaneous deamination of 5-methylcytosine (see Fig. 8-29a) produces thymine, and thus a G–T mismatched pair. These are among the most common mismatches in the DNA of eukaryotes. The specialized repair system restores the G≡C pair.

14. ~1,950 (650 in the DNA degraded between the mismatch and GATC, plus 650 in DNA synthesis to fill the resulting gap, plus 650 in degradation of the pyrophosphate products to inorganic phosphate). ATP is hydrolyzed by the MutSL complex and by the UvrD helicase.

15. (a) UV irradiation produces pyrimidine dimers; in normal fibroblasts, these are excised by cleavage of the damaged strand by a special excinuclease. Thus the denatured single-stranded DNA contains the many fragments created by the cleavage, and the average molecular weight is lowered. These fragments of single-stranded DNA are absent from the XPG samples, as indicated by the unchanged average molecular weight. **(b)** The absence of fragments in the single-stranded DNA from the XPG cells after irradiation suggests the special excinuclease is defective or missing.

16. Most cancerous tumors consist of cells that are deficient in some aspect of DNA repair, relative to the normal surrounding tissue. They thus can be more sensitive to the DNA damaging agent. Tumor cells also tend to be actively dividing, a state in which cells are more sensitive to DNA damage that might be encountered by replication forks.

17. Using G* to represent O^6-meG:

(a) (5′)AACG*TGCAC
TTG T ACGTG

(5′)AACGTGCAC
TTGCACGTG

(b) (5′)AACGTGCAC
TTGCACGTG

(5′)AACGTGCAC
TTGCACGTG

(c) (5′)AACG*TGCAC
TTG T ACGTG

(5′)AACATGCAC
TTGTACGTG

2 × (5′)AACGTGCAC
TTGCACGTG

18. Once paired with a complement after strand invasion, the 3′ end, unlike a 5′ end, can be extended by a DNA polymerase.

19. During homologous genetic recombination, a Holliday intermediate may be formed almost anywhere within the two paired, homologous chromosomes; the branch point of the intermediate can move extensively by branch migration. In site-specific recombination, the Holliday intermediate is formed between two specific sites, and branch migration is generally restricted by heterologous sequences on either side of the recombination sites.

20. (a) Points Y **(b)** Points X

21. Once replication has proceeded from the origin to a point where one recombination site has been replicated but the other has not, site-specific recombination not only inverts the DNA between the recombination sites but also changes the direction of one replication fork relative to the other. The forks will chase each other around the DNA circle, generating many tandem copies of the plasmid. The multimeric circle can be resolved to monomers by additional site-specific recombination events.

22. (a) Even in the absence of an added mutagen, background mutations occur due to radiation, cellular chemical reactions, and so forth. **(b)** If the DNA is sufficiently damaged, a substantial fraction of gene products is nonfunctional and the cell is nonviable. **(c)** Cells with reduced DNA repair capability are more sensitive to mutagens. Because they less readily repair lesions caused by R7000, Uvr$^-$ bacteria have an increased mutation rate and increased chance of lethal effects. **(d)** In the Uvr$^+$ strain, the excision-repair system removes DNA bases with attached [^{3}H]R7000, decreasing the amount of ^{3}H in these cells over time. In the Uvr$^-$ strain, the DNA is not repaired and the ^{3}H level increases as [^{3}H]R7000 continues to react with the DNA.

(e) All mutations listed in the table except A=T to G≡C show significant increases over background. Each type of mutation results from a different type of interaction between R7000 and DNA. Because different types of interactions are not equally likely (due to differences in reactivity, steric constraints, etc.), the resulting mutations occur with different frequencies. **(f)** No. Only those that start with a G≡C base pair are explained by this model. Thus A=T to C≡G and A=T to T=A must be due to R7000 attaching to an A or a T. **(g)** R7000—G pairs with A. First, R7000 adds to G≡C to give R7000—G≡C. (Compare this with what happens with the CH_3—G in Fig. 25-27b.) If this is not repaired, one strand is replicated as R7000—G=A, which is repaired to T=A. The other strand is wild-type. If the replication produces R7000—G=T, a similar pathway leads to an A=T base pair. **(h)** No. Compare data in the two tables, and keep in mind that different mutations occur at different frequencies.

A=T to C≡G: moderate in both strains; but better repair in Uvr$^+$

G≡C to A=T: moderate in both; no real difference

G≡C to C≡G: higher in Uvr$^+$; certainly less repair!

G≡C to T=A: high in both; no real difference

A=T to T=A: high in both; no real difference

A=T to G≡C: low in both; no real difference

Certain adducts may be more readily recognized by the repair apparatus than others, and these are repaired more rapidly and result in fewer mutations.

Chapter 26

1. **(a)** 60 to 100 s **(b)** 500 to 900 nucleotides **(c)** 6 to 11 h

2. A single base error in DNA replication, if not corrected, would cause one of the two daughter cells, and all its progeny, to have a mutated chromosome. A single base error in RNA transcription would not affect the chromosome; it would lead to formation of some defective copies of one protein, but because mRNAs turn over rapidly, most copies of the protein would not be defective. The progeny of this cell would be normal.

3. Normal posttranscriptional processing at the 3′ end (cleavage and polyadenylation) would be inhibited or blocked.

4. Because the template-strand RNA does not encode the enzymes needed to initiate viral infection, it would probably be inert or simply degraded by cellular ribonucleases. Replication of the template-strand RNA and propagation of the virus could occur only if intact RNA replicase (RNA-dependent RNA polymerase) were introduced into the cell along with the template strand.

5. AUGUCCAAAAUCGUA

6. (1) Use of a template strand of nucleic acid; (2) synthesis in the 5′→3′ direction; (3) use of nucleoside triphosphate substrates, with formation of a phosphodiester bond and displacement of PP_i. Polynucleotide phosphorylase forms phosphodiester bonds but differs in all other listed properties.

7. Most of the RNA transcribed in the nucleus was intronic and removed from the mRNAs.

8. No, at this time it is not possible to determine a cell's transcriptome based solely on the genome. Different cells have different transcriptomes based on which promoters are being used and how the transcripts are processed by factors present in the cell.

9. Generally two: one to cleave the phosphodiester bond at one intron-exon junction, the other to link the resulting free exon end to the exon at the other end of the intron. If the nucleophile in the first step were water, this step would be a hydrolysis, and only one transesterification step would be required to complete the splicing process.

10. Many snoRNAs, required for rRNA modification reactions, are encoded in introns. If splicing does not occur, snoRNAs are not produced.

11. **(a)** Water attacks the C-6 position of adenine, forming a tetrahedral intermediate, which then eliminates ammonia to form inosine. **(b)** Inosine can no longer pair correctly with U residues found on the opposite RNA strand prior to ADAR activity. This results in disruption of the RNA duplex. **(c)** Inosine does not have the same pairing properties as adenine and could potentially recode that particular codon so that a different amino acid is incorporated into the protein.

12. Physical separation of the processes prevents translation of primary or precursor transcripts that have not yet been processed by the cell. It also prevents the RNA processing and translational machineries from competing with one another for mRNAs.

13. **(a)** This could change how proteins or other RNAs recognize a particular RNA sequence and interfere with splicing, poly(A) formation, RNA modification, or other steps in which sequence-specific RNA recognition is important. **(b)** *S*-adenosylmethionine serves as the methyl donor in the synthesis of N^6-methyladenosine.

14. These enzymes lack a 3′→5′ proofreading exonuclease and have a high error rate; the likelihood of a replication error that would inactivate the virus is much lower in a small genome than in a large one.

15. **(a)** $4^{36} = 4.7 \times 10^{21}$ **(b)** 0.00002% **(c)** For the "unnatural selection" step, use a chromatographic resin with a bound molecule that is a transition-state analog of the ester hydrolysis reaction.

16. Though RNA synthesis is quickly halted by α-amanitin toxin, it takes several days for the critical mRNAs and proteins in the liver to degrade, causing liver dysfunction and death.

17. **(a)** After lysis of the cells and partial purification of the contents, an antibody-based assay could detect the β subunit. The β subunit could then be subjected to tandem mass spectrometry, which could detect the difference in amino acid residues between the normal β subunit and the mutated form. **(b)** Direct DNA sequencing (by the Sanger method)

18. **(a)** 384 **(b)** 1,620 nucleotide pairs **(c)** Most of the nucleotides are untranslated regions at the 3′ and 5′ ends of the mRNA. Also, most mRNAs code for a signal sequence (Chapter 27) in their protein products, which is eventually removed to produce the mature, functional protein.

19. **(a)** Injection of the antisense oligo cleaves the c-*mos* RNA and removes its poly(A) tail. This correlates with a loss in oocyte maturation. The noncoding poly(A) tail of the c-*mos* mRNA must be important for its function in maturation. **(b)** The sense oligo control shows that these results depend on complementarity to the c-*mos* mRNA. **(c)** The prosthetic RNA likely base-paired with the amputated c-*mos* mRNA and restored its function. Therefore, poly(A) tails can function "in trans"—they do not need to be covalently connected to the mRNAs they regulate. **(d)** The poly(A) tail stimulates protein expression in the reporter. This is likely also occurring with c-*mos*, and this protein expression is important for oocyte maturation. **(e)** These results suggest that the expression of genes can be artificially controlled either by cutting off their poly(A) tails or by attaching synthetic ones derived from other genes. This could be useful for fine-tuning gene expression in bioengineered cells or turning expression on or off.

Chapter 27

1. **(a)** Gly–Gln–Ser–Leu–Leu–Ile **(b)** Leu–Asp–Ala–Pro **(c)** His–Asp–Ala–Cys–Cys–Tyr **(d)** Met–Asp–Glu in eukaryotes; fMet–Asp–Glu in bacteria

2. UUAAUGUAU, UUGAUGUAU, CUUAUGUAU, CUCAUGUAU, CUAAUGUAU, CUGAUGUAU, UUAAUGUAC, UUGAUGUAC, CUUAUGUAC, CUCAUGUAC, CUAAUGUAC, CUGAUGUAC

3. No. Because nearly all the amino acids have more than one codon (e.g., Leu has six), any given polypeptide can be encoded by several different base sequences. However, some amino acids are encoded by only one codon, and those with multiple codons often share the same nucleotide at two of the three positions, so *certain parts* of the mRNA sequence encoding a protein of known amino acid sequence can be predicted with high certainty.

4. (a) (5′)CGACGGCGCGAAGUCAGGGGUGUUAAG(3′) **(b)** Arg–Arg–Glu–Val–Arg–Gly–Val–Lys **(c)** No. The complementary antiparallel strands in double-helical DNA do not have the same base sequence in the 5′→3′ direction. RNA is transcribed from only one specific strand of duplex DNA. The RNA polymerase must therefore recognize and bind to the correct strand.

5. (a), (b), and (c) are correct. **(a)** This outcome would restore the original gene and allow production of the native protein. **(b)** Altering the gene to insert a different amino acid at this position would allow for the generation of a full-length protein. Some activity may be present, especially if the new amino acid represented a conservative alteration (such as Ile substituting for Val). **(c)** This outcome would be similar to (c), inserting an amino acid (probably a different one) at the affected position and allowing synthesis of a full length and perhaps active protein. This outcome is called nonsense suppression. It works because most cells have multiple copies of particular tRNAs, some of which are expressed at low levels. If a minor one is altered, the genetic code is not disrupted because the other copies of the tRNA provide normal function. **(d)** This outcome would rarely work, since it would tend to introduce too many amino acid changes into the protein.

6. The labeled amino acids were found at the carboxyl end. Dintzis only isolated complete α subunits. With short incubation times, labeled amino acids would only appear in the part of the polypeptide that was synthesized last. Labeled amino acids introduced at the amino terminus would not be seen, because those polypeptides would not have been completed prior to protein isolation.

7. There are two tRNAs for methionine: tRNA$^{\text{fMet}}$, which is the initiating tRNA, and tRNA$^{\text{Met}}$, which can insert a Met residue in interior positions in a polypeptide. Only fMet-tRNA$^{\text{fMet}}$ is recognized by the initiation factor IF2 and is aligned with the initiating AUG positioned at the ribosomal P site in the initiation complex. AUG codons in the interior of the mRNA can bind and incorporate only Met-tRNA$^{\text{Met}}$.

8. (5′)AUG-GGU-CGU-GAG-UCA-UCG-UUA-AUU-GUA-GCU-GGA-GGG-GAG-GAA-UGA(3′) is translated as Met–Gly–Arg–Glu–Ser–Ser–Leu–Ile–Val–Ala–Gly–Gly–Glu–Glu. The peptide is 14 amino acids long instead of 15, because the last codon is a stop codon. Ten tRNAs are needed, one for each type of amino acid.

9. Allow polynucleotide phosphorylase to act on a mixture of UDP and CDP in which UDP has, say, five times the concentration of CDP. The result would be a synthetic RNA polymer with many UUU triplets (coding for Phe), a smaller number of UUC (Phe), UCU (Ser), and CUU (Leu), a much smaller number of UCC (Ser), CUC (Leu), and CCU (Pro), and an even smaller number of CCC (Pro).

10. A minimum of 583 ATP equivalents (based on 4 per amino acid residue added, except that there are only 145 translocation steps). Correction of each error requires 2 ATP equivalents. For glycogen synthesis, 292 ATP equivalents are required. The extra energy cost for β-globin synthesis reflects the cost of the information content of the protein. At least 20 activating enzymes, 70 ribosomal proteins, 4 rRNAs, 32 or more tRNAs, an mRNA, and 10 or more auxiliary enzymes must be made by the eukaryotic cell in order to synthesize a protein from amino acids. The synthesis of an (α1→4) chain of glycogen from glucose requires only 4 or 5 enzymes (Chapter 15).

11.

Glycine codons	Anticodons
(5′)GGU	(5′)ACC, GCC, ICC
(5′)GGC	(5′)GCC, ICC
(5′)GGA	(5′)UCC, ICC
(5′)GGG	(5′)CCC, UCC

(a) The 3′ and middle position **(b)** Pairings with anticodons (5′)GCC, ICC, and UCC **(c)** Pairings with anticodons (5′)ACC and CCC

12. (a), (c), (e), and (g) only; (b), (d), and (f) cannot be the result of single-base mutations, because (b) and (f) would require substitutions of two bases, and (d) would require substitutions of all three bases.

```
13. (5′)AUGAUAUUGCUAUCUUGGACU
    Changes: CC AU U C      C
             U     C A      A
                   G G      G
```

Of 63 possible one-base changes, 14 would result in no coding change.

14. The two DNA codons for Glu are GAA and GAG, and the four DNA codons for Val are GTT, GTC, GTA, and GTG. A single base change in GAA to form GTA or in GAG to form GTG could account for the Glu → Val replacement in sickle-cell hemoglobin. Much less likely are two-base changes, from GAA to GTG, GTT, or GTC; and from GAG to GTA, GTT, or GTC.

15. Isoleucine is similar in structure to several other amino acids, particularly valine. Distinguishing between valine and isoleucine in the aminoacylation process requires a second filter—a proofreading function. Histidine has a structure unlike that of any other amino acid, providing opportunities for binding specificity adequate to ensure accurate aminoacylation of the cognate tRNA.

16. (a) The Ala-tRNA synthetase recognizes the G^3–U^{70} base pair in the amino acid arm of tRNA$^{\text{Ala}}$. **(b)** The mutant tRNA$^{\text{Ala}}$ would insert Ala residues at codons encoding Pro. **(c)** A mutation that might have similar effects is an alteration in tRNA$^{\text{Pro}}$ that allowed it to be recognized and aminoacylated by Ala-tRNA synthetase. **(d)** Most of the proteins in the cell would be inactivated, so these would be lethal mutations and hence never observed. This represents a powerful selective pressure for maintaining the genetic code.

17. The 15,000 ribosomes in an *E. coli* cell can synthesize more than 23,000 proteins in 20 minutes.

18. *IF2:* The 70S ribosome would form, but initiation factors would not be released and elongation could not start. *EF-Tu:* The second aminoacyl-tRNA would bind to the ribosomal A site, but no peptide bond would form. *EF-G:* The first peptide bond would form, but the ribosome would not move along the mRNA to vacate the A site for binding of a new EF-Tu–tRNA.

19. The amino acid most recently added to a growing polypeptide chain is the only one covalently attached to a tRNA and thus is the only link between the polypeptide and the mRNA encoding it. A proofreading activity would sever this link, halting synthesis of the polypeptide and releasing it from the mRNA.

20. SecA; Drugs that inhibit the ability of SecA to bind bacterial proteins or hydrolyze ATP could significantly disrupt the export of bacterial proteins. SecB is nonessential as bacteria have numerous other chaperone proteins. Antibiotics that target the SecYEG complex, which is homologous to its eukaryotic counterpart (Sec61), could cause significant adverse effects in humans.

21. The protein would be directed into the ER, and from there the targeting would depend on additional signals. SRP binds the amino-terminal signal early in protein synthesis and directs the nascent polypeptide and ribosome to receptors in the ER. Because the protein is translocated into the lumen of the ER as it is synthesized, the NLS is never accessible to the proteins involved in nuclear targeting.

22. Trigger factor is a molecular chaperone that stabilizes an unfolded and translocation-competent conformation of ProOmpA.

23. DNA with a minimum of 5,784 bp; some of the coding sequences must be nested or overlapping.

24. (a) The helices associate through the hydrophobic effect and van der Waals interactions. **(b)** R groups 3, 6, 7, and 10 extend to the left; 1, 2, 4, 5, 8, and 9 extend to the right. **(c)** One possible sequence is

1 2 3 4 5 6 7 8 9 10
N–Phe–Ile–Glu–Val–Met–Asn–Ser–Ala–Phe–Gln–*C*

(d) One possible DNA sequence for the amino acid sequence in (c) is

Nontemplate strand

Template strand

(e) Phe, Leu, Ile, Met, and Val. All are hydrophobic, but the set does not include *all* the hydrophobic amino acids; Trp, Pro, and Ala are missing. **(f)** Tyr, His, Gln, Asn, Lys, Asp, and Glu. All of these are hydrophilic, although Tyr is less hydrophilic than the others. The set does not include *all* the hydrophilic amino acids; Ser, Thr, and Arg are missing. **(g)** Omitting T from the mixture excludes codons starting or ending with T—thus excluding Tyr, which is not very hydrophilic, and, more importantly, excluding the two possible stop codons (TAA and TAG). No other amino acids in the NAN set are excluded by omitting T. **(h)** Misfolded proteins are often degraded in the cell. Therefore, if a synthetic gene has produced a protein that forms a band on the SDS gel, it is likely that this protein is folded properly. **(i)** Protein folding depends on more than the hydrophobic effect and van der Waals interactions. There are many reasons why a synthesized random-sequence protein might not fold into the four-helix structure. For example, hydrogen bonds between hydrophilic side chains could disrupt the structure. Also, not all sequences have an equal propensity to form an α helix.

Chapter 28

1. (a) Tryptophan synthase levels remain high despite the presence of tryptophan. **(b)** Levels again remain high. **(c)** Levels rapidly decrease, preventing wasteful synthesis of tryptophan.

2. The *E. coli* cells will produce β-galactosidase when they are subjected to high levels of a DNA-damaging agent such as UV light. Under such conditions, RecA binds to single-stranded chromosomal DNA and facilitates autocatalytic cleavage of the LexA repressor, releasing LexA from its binding site and allowing transcription of downstream genes.

3. (a) Constitutive, low-level expression of the operon; most mutations in the operator would make the repressor less likely to bind. **(b)** Constitutive expression; mutation prevents negative regulation of the operon. **(c)** Increased expression; under conditions in which the operon is induced, mutation increases recruitment of RNA polymerase. **(d)** Constant repression; mutation allows repressor to readily bind to operator. **(e)** Decreased expression; under conditions in which the operon is induced, mutation decreases recruitment of RNA polymerase.

4. 7,000 copies

5. 8×10^{-9} M, about 10^5 times greater than the dissociation constant. With 10 copies of active repressor in the cell, the operator site is always bound by the repressor molecule.

6. (a) through **(e)**. Each condition decreases expression of *lac* operon genes.

7. (a) Less attenuation. The ribosome completing the translation of sequence 1 would no longer overlap and block sequence 2; sequence 2 would always be available to pair with sequence 3, preventing formation of the attenuator structure. **(b)** More attenuation. Sequence 2 would pair less efficiently with sequence 3; the attenuator structure would be formed more often, even when sequence 2 was not blocked by a ribosome. **(c)** No attenuation. The only regulation would be that afforded by the Trp repressor. **(d)** Attenuation loses its sensitivity to Trp tRNA. It might become sensitive to His tRNA. **(e)** Attenuation would rarely, if ever, occur. Sequences 2 and 3 always block formation of the attenuator. **(f)** Constant attenuation. Attenuator always forms, regardless of the availability of tryptophan.

8. Induction of the SOS response could not occur, making the cells more sensitive to high levels of DNA damage.

9. Each *Salmonella* cell would have flagella made up of both types of flagellar protein, and the cell would be vulnerable to antibodies generated in response to either protein.

10. A dissociable factor necessary for activity (e.g., a specificity factor similar to the σ subunit of the *E. coli* enzyme) may have been lost during purification of the polymerase.

11.

Gal4 protein

Gal4p DNA-binding domain	Gal4p activator domain

Engineered protein

Lac repressor DNA-binding domain	Gal4p activator domain

The engineered protein cannot bind to the Gal4p-binding site in the *GAL* gene (UAS_G) because it lacks the Gal4p DNA-binding domain. Modify the Gal4p-binding site in the DNA to give it the nucleotide sequence to which the Lac repressor normally binds (using methods described in Chapter 9).

12. Methylamine. The reaction proceeds with attack of water on the guanidinium carbon of the modified arginine.

13. Synthesis of a protein first requires the synthesis of an mRNA long enough to encode the protein and to include any necessary regulatory sequences, with one ribonucleoside triphosphate used up for every nucleotide residue included in the mRNA. Then, the mRNA must be translated—one of the most energy-intensive processes in the cell (Chapter 27). To maintain repression, the repressor protein would need to be synthesized repeatedly. With the use of RNA as repressor, the RNA can be shorter than a protein repressor–encoding mRNA, and no translation step is required.

14. The *bcd* mRNA needed for development is contributed to the egg by the mother. The fertilized egg develops normally even if its genotype is *bcd*$^-$/*bcd*$^-$, as long as the mother has one normal *bcd* gene and the *bcd*$^-$ allele is recessive. However, the adult *bcd*$^-$/*bcd*$^-$ female will be sterile because she has no normal *bcd* mRNA to contribute to her eggs.

15. (a) For 10% expression (90% repression), 10% of the repressor has bound inducer and 90% is free and available to bind the operator. The calculation uses Eqn 5-8 (p. 151), with $Y = 0.1$ and $K_\text{d} = 10^{-4}$ M:

$$Y = \frac{[\text{IPTG}]}{[\text{IPTG}] + K_\text{d}} = \frac{[\text{IPTG}]}{[\text{IPTG}] + 10^{-4}\ \text{M}}$$

$$0.1 = \frac{[\text{IPTG}]}{[\text{IPTG}] + 10^{-4}\ \text{M}}$$

$$0.9[\text{IPTG}] = 10^{-5} \qquad \text{or} \qquad [\text{IPTG}] = 1.1 \times 10^{-5}\ \text{M}$$

For 90% expression, 90% of the repressor has bound inducer, so $Y = 0.9$. Entering the values for Y and K_d in Eqn 5-8 gives $[\text{IPTG}] = 9 \times 10^{-4}$ M. Thus, gene expression varies 10-fold over a roughly 10-fold [IPTG] range. **(b)** You would expect the protein levels to be low before induction, to rise during induction, and then to decay as synthesis stops and the proteins are degraded. **(c)** As shown in (a), the *lac* operon has more levels of expression than just on or off; thus it does not have characteristic A. As shown in (b), expression of the *lac* operon subsides once the inducer is removed; thus it lacks characteristic B. **(d)** *GFP-on:* rep^{ts} (designating the protein product of the *rep*^{ts} gene) and GFP are expressed at high levels; rep^{ts} represses OP$_\lambda$, so no LacI is produced. *GFP-off:* LacI is expressed at a high level; LacI represses OP$_{lac}$, so rep^{ts} and GFP are not produced. **(e)** IPTG treatment switches the system from GFP-off to GFP-on. IPTG has an effect only when LacI is present, so it affects only the GFP-off state. Adding IPTG relieves the repression of OP$_{lac}$, allowing high-level expression of rep^{ts}, which turns off expression of LacI, and high-level expression of GFP. **(f)** Heat treatment switches the system from GFP-on to GFP-off. Heat has an effect only when rep^{ts} is present, so affects only the GFP-on state. Heat inactivates rep^{ts} and relieves the repression of OP$_\lambda$, allowing high-level expression of LacI. LacI then acts at OP$_{lac}$ to repress synthesis of rep^{ts} and GFP. **(g)** *Characteristic A:* The system is not stable in the intermediate state. At some point, one repressor will act more strongly than the other due to chance fluctuations in expression; this shuts off expression of the other repressor and locks the system in one state. *Characteristic B:* Once one repressor is expressed, it prevents the synthesis of the other; thus the system remains in one state even after the switching stimulus has been removed. **(h)** At no time does any cell express an intermediate level of GFP—this is a confirmation of characteristic A. At the intermediate concentration (X) of inducer, some cells have switched to GFP-on while others have not yet made the switch and remain in the GFP-off state; none are in between. The bimodal distribution of expression levels at [IPTG] = X is caused by the mixed population of GFP-on and GFP-off cells.

Glossary

a

ABC transporters: Plasma membrane proteins with sequences that make up *A*TP-*b*inding *c*assettes; serve to transport a large variety of substrates, including inorganic ions, lipids, and nonpolar drugs, out of the cell, using ATP as the energy source.

absolute configuration: The configuration of four different substituent groups around an asymmetric carbon atom, in relation to D- and L-glyceraldehyde.

absorption: Transport of the products of digestion from the intestinal tract into the blood.

acceptor control: Regulation of the rate of respiration by the availability of ADP as phosphate group acceptor.

accessory pigments: Visible light–absorbing pigments (carotenoids, xanthophylls, and phycobilins) in plants and photosynthetic bacteria that complement chlorophylls in trapping energy from sunlight.

acid dissociation constant: The dissociation constant (K_a) of an acid, describing its dissociation into its conjugate base and a proton.

acidosis: A metabolic condition in which the capacity of the body to buffer H^+ is diminished; usually accompanied by decreased blood pH. *Compare* alkalosis.

actin: A protein that makes up the thin filaments of muscle; also an important component of the cytoskeleton of many eukaryotic cells.

action spectrum: A plot of the efficiency of light at promoting a light-dependent process such as photosynthesis as a function of wavelength.

activation energy ($\Delta G^\ddagger$): The amount of energy (in joules) required to convert all the molecules in 1 mol of a reacting substance from the ground state to the transition state.

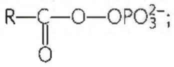
activator: (1) A DNA-binding protein that positively regulates the expression of one or more genes; that is, transcription rates increase when an activator is bound to the DNA. (2) A positive modulator of an allosteric enzyme.

active site: The region of an enzyme surface that binds the substrate molecule and catalytically transforms it; also known as the catalytic site.

active transporter: Membrane protein that moves a solute across a membrane against an electrochemical gradient in an energy-requiring reaction.

activity: The true thermodynamic activity or potential of a substance, as distinct from its molar concentration.

acyl phosphate: Any molecule with the general chemical form



$R{-}\underset{\underset{O}{\|}}{C}{-}O{-}OPO_3^{2-}$;

an acid anhydride between a carboxylic acid and phosphoric acid.

adaptor proteins: Signaling proteins, generally lacking enzymatic activities, that have binding sites for two or more cellular components and serve to bring those components together.

adenosine 3′,5′-cyclic monophosphate: *See* cyclic AMP.

adenosine diphosphate: *See* ADP.

adenosine triphosphate: *See* ATP.

***S*-adenosylmethionine (adoMet):** An enzymatic cofactor involved in methyl group transfers.

adenylate kinase: The enzyme that catalyzes the reversible reaction ATP + AMP → 2 ADP. When anabolic activities have depleted the supply of ATP, this enzyme produces more ATP from ADP. Also called myokinase. *Compare* nucleoside monophosphate kinase.

adipocyte: An animal cell specialized for the storage of fats (triacylglycerols).

adipose tissue: Connective tissue specialized for the storage of large amounts of triacylglycerols. *See also* beige adipose tissue; brown adipose tissue; white adipose tissue.

ADP (adenosine diphosphate): A ribonucleoside 5′-diphosphate serving as phosphate group acceptor in the cell energy cycle.

adoMet: *See S*-adenosylmethionine.

aerobe: An organism that lives in air and uses oxygen as the terminal electron acceptor in respiration.

aerobic: Requiring or occurring in the presence of oxygen.

aerobic glycolysis: Cellular energy generation by glycolysis alone (without subsequent oxidation of pyruvate) even though oxygen is available. *See* glycolysis.

agonist: A compound, typically a hormone or neurotransmitter, that elicits a physiological response when it binds to its specific receptor.

AKAPs (A kinase anchoring proteins): A family of proteins that share a domain that binds the R subunit of protein kinase A (PKA). Each also has a domain with affinity for one of a number of diverse proteins, so that each AKAP anchors PKA in a specific location or to a specific protein.

alcohol fermentation: *See* ethanol fermentation.

aldose: A simple sugar in which the carbonyl carbon atom is an aldehyde; that is, the carbonyl carbon is at one end of the carbon chain.

alkalosis: A metabolic condition in which the capacity of the body to buffer OH^- is diminished; usually accompanied by an increase in blood pH. *Compare* acidosis.

allosteric enzyme: A regulatory enzyme with catalytic activity modulated by the noncovalent binding of a specific metabolite at a site other than the active site.

allosteric protein: A protein (generally with multiple subunits) with multiple ligand-binding sites, such that ligand binding at one site affects ligand binding at another.

allosteric site: The specific site on the surface of an allosteric protein molecule to which the modulator or effector molecule binds.

α helix: A helical conformation of a polypeptide chain, usually right-handed, with maximal intrachain hydrogen bonding; one of the most common secondary structures in proteins.

α oxidation: An alternative path for the oxidation of β-methyl fatty acids in peroxisomes, as distinct from β oxidation and ω oxidation.

alternative splicing: A process in which exons are selectively spliced (linked) in alternative ways to generate different mature mRNAs.

Ames test: A simple bacterial test for carcinogenicity, based on the assumption that carcinogens are mutagens.

amino acid activation: ATP-dependent enzymatic esterification of the carboxyl group of an amino acid to the 3′-hydroxyl group of its corresponding tRNA.

amino acids: α-Amino–substituted carboxylic acids, the building blocks of proteins.

aminoacyl-tRNA: An aminoacyl ester of a tRNA.

aminoacyl-tRNA synthetases: Enzymes that catalyze synthesis of an aminoacyl-tRNA at the expense of ATP energy.

amino-terminal residue: The only amino acid residue in a polypeptide chain that has a free α-amino group; defines the amino terminus of the polypeptide.

aminotransferases: Enzymes that catalyze the transfer of amino groups from α-amino to α-keto acids; also called transaminases.

ammonotelic: Excreting excess nitrogen in the form of ammonia.

AMP-activated protein kinase (AMPK): A protein kinase allosterically activated by 5′-adenosine monophosphate (AMP) and inhibited by ATP. AMPK action generally shifts metabolism away from biosynthesis toward energy production.

amphibolic pathway: A metabolic pathway used in both catabolism and anabolism.

amphipathic: Containing both polar and nonpolar domains.

amphitropic proteins: Proteins that associate reversibly with the membrane and thus can be found in the cytosol, in the membrane, or in both places.

ampholyte: A substance that can act as either a base or an acid.

amphoteric: Capable of donating and accepting protons, thus able to serve as an acid or a base.

AMPK: *See* AMP-activated protein kinase.

amyloidoses: A variety of progressive diseases characterized by abnormal deposits of misfolded proteins in one or more organs or tissues.

anabolism: The phase of intermediary metabolism concerned with the energy-requiring biosynthesis of cell components from smaller precursors, typically a reductive process.

anaerobe: An organism that lives without oxygen. Obligate anaerobes die when exposed to oxygen.

anaerobic: Occurring in the absence of air or oxygen.

analyte: A molecule to be analyzed by mass spectrometry.

anammox: Anaerobic oxidation of ammonia to N_2, using nitrite as electron acceptor; carried out by specialized chemolithotrophic bacteria.

anaplerotic reaction: An enzyme-catalyzed reaction that can replenish the supply of intermediates in the citric acid cycle.

angstrom (Å): A unit of length (10^{-8} cm) used to indicate molecular dimensions. 10 Å = 1 nm.

anhydride: The product of the condensation of two carboxyl or phosphate groups in which the elements of water are eliminated to form a compound with the general structure  $R-\underset{\underset{O}{\|}}{X}-O-\underset{\underset{O}{\|}}{X}-R$, where X is either carbon or phosphorus.

anion-exchange resin: A polymeric resin with fixed cationic groups, used in the chromatographic separation of anions.

anomeric carbon: The carbon atom in a sugar at the new chiral center formed when a sugar cyclizes to form a hemiacetal. This is the carbonyl carbon of aldehydes and ketones.

anomers: Two stereoisomers of a given sugar that differ only in the configuration about the carbonyl (anomeric) carbon atom.

anorexigenic: Tending to decrease appetite and food consumption. *Compare* orexigenic.

antagonist: A compound that interferes with the physiological action of another substance (the agonist), usually at a hormone or neurotransmitter receptor.

antibiotic: One of many different organic compounds that are formed and secreted by various species of microorganisms and plants, are toxic to other microbial species, and presumably have a defensive function.

antibody: A defense protein synthesized by the immune system of vertebrates and circulated in the blood. *See also* immunoglobulin.

anticodon: A specific sequence of three nucleotides in a tRNA, complementary to a codon for an amino acid in an mRNA.

antigen: A molecule capable of eliciting the synthesis of a specific antibody in vertebrates.

antiparallel: Describes two linear polymers that are opposite in polarity or orientation.

antiport: Cotransport of two solutes across a membrane in opposite directions.

apoenzyme: The protein portion of an enzyme, exclusive of any organic or inorganic cofactors or prosthetic groups that might be required for catalytic activity.

apolipoprotein: The protein component of a lipoprotein.

apoprotein: The protein portion of a protein, exclusive of any organic or inorganic cofactors or prosthetic groups that might be required for activity.

apoptosis: Process in which a cell in an organism brings about its own death and lysis, in response to a signal from outside or programmed in its genes, by systematically degrading its own macromolecules for salvage by the organism.

aptamer: An oligonucleotide that binds specifically to one molecular target, usually selected by an iterative cycle of affinity-based enrichment (SELEX).

aquaporins (AQPs): A family of integral membrane proteins that mediate the flow of water across membranes.

archaea: Members of Archaea, one of the three domains of living organisms; include many species that thrive in extreme environments of high ionic strength, high temperature, or low pH.

arcuate nucleus: A group of neurons in the hypothalamus that function in regulation of hunger and feeding behavior.

asymmetric carbon atom: A carbon atom that is covalently bonded to four different groups and thus may exist in two different tetrahedral configurations.

ATP (adenosine triphosphate): A ribonucleoside 5′-triphosphate functioning as a phosphate group donor in the cellular energy cycle; carries chemical energy between metabolic pathways by serving as a shared intermediate coupling endergonic and exergonic reactions.

ATPase: An enzyme that hydrolyzes ATP to yield ADP and phosphate, usually coupled to a process requiring energy.

ATP synthase: An enzyme complex that forms ATP from ADP and phosphate during oxidative phosphorylation in the inner mitochondrial membrane or the bacterial plasma membrane, and during photophosphorylation in chloroplasts.

attenuator: An RNA sequence involved in regulating the expression of certain genes; functions as a transcription terminator.

autophagy: Catabolic lysosomal degradation of cellular proteins and other components.

autophosphorylation: Strictly, the phosphorylation of an amino acid residue in a protein that is catalyzed by the same protein molecule; often extended to include phosphorylation of one subunit of a homodimer by the other subunit.

autotroph: An organism that can synthesize its own complex molecules from very simple carbon and nitrogen sources, such as carbon dioxide and ammonia.

auxin: A plant growth hormone.

auxotrophic mutant (auxotroph): A mutant organism defective in the synthesis of a particular biomolecule, which must therefore be supplied for the organism's growth.

Avogadro's number (*N*): The number of molecules in a gram molecular weight (a mole) of any compound (6.02×10^{23}).

b

bacteria: Members of Bacteria, one of the three domains of living organisms; they have a plasma membrane but no internal organelles or nucleus.

bacteriophage: A virus capable of replicating in a bacterial cell; also called a phage.

baculovirus: Any of a group of double-stranded DNA viruses that infect invertebrates, particularly insects; widely used for protein expression in biotechnology.

Barr body: A condensed, inactive form of the X chromosome found in the cells of female mammals.

basal metabolic rate: An animal's rate of oxygen consumption when at complete rest, long after a meal.

base pair: Two nucleotides in nucleic acid chains that are paired by hydrogen bonding of their bases; for example, A with T or U, and G with C.

BAT: *See* brown adipose tissue.

B cell: *See* B lymphocyte.

beige adipose tissue: Thermogenic adipose tissue activated by cooling of the individual; expresses the uncoupling protein UCP1 (thermogenin) at a high level. *Compare* brown adipose tissue; white adipose tissue.

β conformation: An extended, zigzag arrangement of a polypeptide chain; a common secondary structure in proteins.

β oxidation: Oxidative degradation of fatty acids into acetyl-CoA by successive oxidations at the β-carbon atom; as distinct from α oxidation and ω oxidation.

β sheet: The side-by-side, hydrogen-bonded arrangement of polypeptide chains in the extended β conformation.

β turn: A type of protein secondary structure consisting of four amino acid residues arranged in a tight turn so that the polypeptide turns back on itself.

bilayer: A double layer of oriented amphipathic lipid molecules, forming the basic structure of biological membranes. The hydrocarbon tails face inward to form a continuous nonpolar phase.

bile acids: Polar derivatives of cholesterol, secreted by the liver into the intestine, that serve to emulsify dietary fats, facilitating lipase action.

bile salts: Amphipathic steroid derivatives with detergent properties, participating in digestion and absorption of lipids.

binding energy (ΔG_B): The energy derived from noncovalent interactions between enzyme and substrate or receptor and ligand.

binding site: The crevice or pocket on a protein in which a ligand binds.

bioassay: A method for measuring the amount of a biologically active substance (such as a hormone) in a sample by quantifying the biological response to aliquots of that sample.

biochemical standard free-energy change ($\Delta G'^{\circ}$): The free-energy change for a reaction occurring under a set of standard conditions: temperature, 298 K; pressure, 1 atm (101.3 kPa); all solutes at 1 M concentration; at pH 7.0 in 55.5 M water. Also called standard transformed free-energy change. *Compare* standard free-energy change (ΔG°).

biochemistry: A molecular description of the structures, mechanisms, and chemical processes of living things in all their diverse forms.

bioinformatics: The computerized analysis of biological data, using methods derived from statistics, linguistics, mathematics, chemistry, biochemistry, and physics. The data are often nucleic acid or protein sequences or structural data.

biosphere: All the places on or in the earth, the seas, and the atmosphere occupied by living matter.

biotin: A vitamin; an enzymatic cofactor in carboxylation reactions.

B lymphocyte (B cell): One of a class of blood cells (lymphocytes), responsible for the production of circulating antibodies.

body mass index (BMI): A measure of obesity, calculated as weight in kilograms divided by (height in meters)^2. A BMI of more than 27.5 is defined as overweight; more than 30, as obese.

bond energy: The energy required to break a bond.

branch migration: Movement of the branch point in a branched DNA formed from two DNA molecules with identical sequences. *See also* Holliday intermediate.

brown adipose tissue (BAT): Thermogenic adipose tissue rich in mitochondria that contain the uncoupling protein UCP1 (thermogenin), which uncouples electron transfer through the respiratory chain from ATP synthesis. *Compare* beige adipose tissue; white adipose tissue.

buffer: A system capable of resisting changes in pH, consisting of a conjugate acid-base pair in which the ratio of proton acceptor to proton donor is near unity.

C

C_3 plants: Plants in which the first product of CO_2 fixation is the three-carbon compound 3-phosphoglycerate. *Compare* C_4 plants.

C_4 pathway: The metabolic pathway in which CO_2 is first added to phosphoenolpyruvate by the enzyme PEP carboxylase to produce the four-carbon compound within mesophyll cells that is later transported to the bundle-sheath cells, where the CO_2 is released for use in the Calvin cycle.

C_4 plants: Plants (generally tropical) in which CO_2 is first fixed into a four-carbon compound, oxaloacetate or malate, before entering the Calvin cycle via the rubisco reaction. *Compare* C_3 plants.

calorie: The amount of heat required to raise the temperature of 1.0 g of water from 14.5 to 15.5 °C. One calorie (cal) equals 4.18 joules (J). The nutritional calorie, Cal, is equal to 1,000 calories, or 1 kcal.

Calvin cycle: The cyclic pathway in plants that fixes carbon dioxide and produces triose phosphates.

CAM plants: Succulent plants of hot, dry climates, in which CO_2 is fixed into oxaloacetate in the dark, then fixed by rubisco in the light when stomata close to exclude O_2.

cAMP: *See* cyclic AMP.

cAMP receptor protein (CRP): In bacteria, a specific regulatory protein that controls initiation of transcription of the genes that produce the enzymes required to use some other nutrient when glucose is lacking; also called catabolite gene activator protein (CAP).

cAMP-dependent protein kinase (protein kinase A; PKA): A protein kinase that phosphorylates Ser or Thr residues when bound by its allosteric activator, cAMP.

CAP: *See* cAMP receptor protein.

capsid: The protein coat of a virion, or virus particle.

carbanion: A negatively charged carbon atom.

carbocation: A positively charged carbon atom; also called a carbonium ion.

carbohydrate: A polyhydroxy aldehyde or ketone, or substance that yields such a compound on hydrolysis. Many carbohydrates have the empirical formula $(CH_2O)_n$; some also contain nitrogen, phosphorus, or sulfur.

carbon-assimilation reactions: Formerly referred to as dark reactions. *See* CO_2 assimilation.

carbon fixation: *See* CO_2 fixation.

carbonium ion: *See* carbocation.

carboxyl-terminal domain (CTD): The carboxyl-terminal domain of eukaryotic RNA polymerase II, containing many repeats of the heptapeptide YSPTSPS. Phosphorylation of the CTD changes during transcription. Many cellular factors interact with the CTD to regulate gene expression.

carboxyl-terminal residue: The only amino acid residue in a polypeptide chain that has a free α-carboxyl group; defines the carboxyl terminus of the polypeptide.

cardiolipin: A membrane phospholipid in which two phosphatidic acid moieties share a single glycerol head group.

carnitine shuttle: A mechanism for moving fatty acids from the cytosol to the mitochondrial matrix as fatty esters of carnitine.

carotenoids: Lipid-soluble photosynthetic pigments made up of isoprene units.

cascade: *See* enzyme cascade; regulatory cascade.

catabasis: Resolution of inflammation.

catabolism: The phase of intermediary metabolism concerned with the energy-yielding degradation of nutrient molecules, typically an oxidative process.

catabolite gene activator protein (CAP): *See* cAMP receptor protein.

catalytic site: *See* active site.

catecholamines: Hormones, such as epinephrine, that are amino derivatives of catechol.

catenane: Two or more circular polymeric molecules interlinked by one or more noncovalent topological links, resembling the links of a chain.

cation-exchange resin: An insoluble polymer with fixed negative charges, used in the chromatographic separation of cationic substances.

CD spectroscopy: *See* circular dichroism spectroscopy.

cDNA: *See* complementary DNA.

cDNA library: A collection of cloned DNA fragments derived entirely from the complement of mRNA being expressed in a particular organism or cell type under a defined set of conditions.

cellular differentiation: The process in which a precursor cell becomes specialized to carry out a particular function, by acquiring a new complement of proteins and RNA.

central dogma: An organizing principle of molecular biology that is now accepted as fact rather than dogma: genetic information flows between nucleic acids and from nucleic acid to protein, but not from protein to nucleic acid or from protein to protein.

centromere: A specialized site in a chromosome, serving as the attachment point for the mitotic or meiotic spindle.

cerebroside: A sphingolipid containing one sugar residue as a head group.

channeling: *See* substrate channeling.

chaperone: Any of several classes of proteins or protein complexes that catalyze the accurate folding of proteins in all cells.

chaperonin: One of two major classes of chaperones in virtually all organisms; a complex of proteins that functions in protein folding: GroES/GroEL in bacteria; Hsp60 in eukaryotes.

chemiosmotic coupling: Coupling of ATP synthesis to electron transfer by a transmembrane difference in charge and pH.

chemiosmotic theory: The theory that energy derived from electron transfer reactions is temporarily stored as a transmembrane difference in charge and pH, which subsequently drives formation of ATP in oxidative phosphorylation and photophosphorylation.

chemotaxis: A cell's sensing of and movement toward or away from a specific chemical agent.

chemotroph: An organism that obtains energy by metabolizing organic compounds derived from other organisms.

chiral center: An atom with substituents arranged so that the molecule is not superposable on its mirror image.

chiral compound: A compound that contains an asymmetric center (chiral atom or chiral center) and thus can occur in two nonsuperposable mirror-image forms (enantiomers).

chlorophylls: A family of green pigments that function as receptors of light energy in photosynthesis; magnesium-porphyrin complexes.

chloroplast: A chlorophyll-containing photosynthetic organelle in some eukaryotic cells.

chondroitin sulfate: One of a family of sulfated glycosaminoglycans, a major component of the extracellular matrix.

chromatin: A filamentous complex of DNA, histones, and other proteins, constituting the eukaryotic chromosome.

chromatography: A process in which complex mixtures of molecules are separated by many repeated partitionings between a flowing (mobile) phase and a stationary phase.

chromatophore: A compound or moiety (natural or synthetic) that absorbs visible or ultraviolet light.

chromosome: A single large DNA molecule and its associated proteins and often associated regulatory or structural RNA; containing many genes; stores and transmits genetic information.

chromosome territory: A region of the nucleus preferentially occupied by a particular chromosome.

chylomicron: A plasma lipoprotein consisting of a large droplet of triacylglycerols stabilized by a coat of protein and phospholipid; carries lipids from the intestine to tissues.

circular dichroism (CD) spectroscopy: A method used to characterize the degree of folding in a protein, based on differences in the absorption of right-handed versus left-handed circularly polarized light.

cis-trans isomers: *See* geometric isomers.

cistron: A unit of DNA or RNA corresponding to one gene.

citric acid cycle: A cyclic pathway for the oxidation of acetyl residues to carbon dioxide, in which formation of citrate is the first step; also known as the Krebs cycle or tricarboxylic acid cycle.

Cleland nomenclature: A shorthand notation developed by W. W. Cleland for describing the progress of enzymatic reactions with multiple substrates and products.

clones: The descendants of a single cell.

cloning: The production of large numbers of identical DNA molecules, cells, or organisms from a single, ancestral DNA molecule, cell, or organism.

closed system: A system that exchanges neither matter nor energy with the surroundings. *See also* system.

CO_2 assimilation: Reaction sequence in which atmospheric CO_2 is converted into organic compounds.

cobalamin: *See* coenzyme B_{12}.

coding strand: In DNA transcription, the DNA strand identical in base sequence to the RNA transcribed from it, with U in the RNA in place of T in the DNA; as distinct from the template strand. Also called the nontemplate strand.

codon: A sequence of three adjacent nucleotides in a nucleic acid that codes for a specific amino acid.

coenzyme: An organic cofactor required for the action of certain enzymes; often is synthesized from a vitamin.

coenzyme A: A coenzyme with two sulfhydryl groups that serve both as acyl group carriers and redox cofactors.

coenzyme B_{12}: An enzymatic cofactor derived from the vitamin cobalamin, involved in certain types of carbon skeletal rearrangements.

cofactor: An inorganic ion or a coenzyme required for enzyme activity.

CO_2 fixation: The reaction, catalyzed by rubisco during photosynthesis or by other carboxylases, in which atmospheric CO_2 is initially incorporated (fixed) into an organic compound.

cognate: Describes two biomolecules that normally interact; for example, an enzyme and its usual substrate, or a receptor and its usual ligand.

cohesive ends: *See* sticky ends.

cointegrate: An intermediate in the migration of certain DNA transposons in which the donor DNA and target DNA are covalently attached.

colligative properties: The properties of a solution that depend on the number of solute particles per unit volume; for example, freezing-point depression.

combinatorial control: The use of combinations of a limited repertoire of regulatory proteins to provide gene-specific regulation of many individual genes.

comparative genomics: A discipline in which genomic information is compared within one organism or between two species or many. Comparisons may focus on, but are not limited to, gene sequences, gene order on a chromosome, regulatory sequences, gene modifications, and gene evolution.

competitive inhibition: A type of enzyme inhibition reversed by increasing the substrate concentration; a competitive inhibitor generally competes with the normal substrate or ligand for a protein's binding site.

complementary: Having a molecular surface with chemical groups arranged to interact specifically with chemical groups on another molecule.

complementary DNA (cDNA): A DNA complementary to a specific RNA, usually made through the use of reverse transcriptase.

Complex I: Respiratory chain complex that catalyzes the transfer to ubiquinone of a hydride ion from NADH and a proton from the mitochondrial matrix, coupled to the transfer of four protons from the matrix to the intermembrane space. Complex I is composed of 45 different polypeptide chains, including an FMN-containing flavoprotein and at least 8 iron-sulfur centers. Also called NADH:ubiquinone oxidoreductase and NADH dehydrogenase.

Complex II: Membrane-bound respiratory chain complex and citric acid cycle component that couples the oxidation of succinate with the reduction of ubiquinone. Complex II has four different protein subunits, a heme group, three 2Fe-2S centers, bound FAD, and binding sites for succinate and ubiquinone. Also called succinate dehydrogenase.

Complex III: Respiratory chain complex that couples the transfer of electrons from ubiquinol to cytochrome *c* with the vectorial transport of protons from the matrix to the intermembrane space (from the cytosol to the periplasmic space in bacteria). Complex III functions as a homodimer; each monomer consists of three proteins: cytochrome *b*, cytochrome c_1, and the Rieske iron-sulfur protein. Also called cytochrome bc_1 complex and ubiquinone:cytochrome *c* oxidoreductase.

Complex IV: Respiratory chain complex that carries electrons from cytochrome *c* to molecular oxygen, reducing it to H_2O. Also called cytochrome oxidase.

condensation: A reaction type in which two compounds are joined with the elimination of water.

configuration: The spatial arrangement of an organic molecule conferred by the presence of (1) double bonds, about which there is no freedom of rotation, or (2) chiral centers, around which substituent groups are arranged in a specific sequence. Configurational isomers cannot be interconverted without breaking one or more covalent bonds.

conformation: A spatial arrangement of substituent groups that are free to assume different positions in space, without breaking any bonds, because of the freedom of bond rotation.

conjugate acid-base pair: A proton donor and its corresponding deprotonated species; for example, acetic acid (donor) and acetate (acceptor).

conjugated protein: A protein containing one or more prosthetic groups.

conjugate redox pair: An electron donor and its corresponding electron acceptor; for example, Cu^+ (donor) and Cu^{2+} (acceptor), or NADH (donor) and NAD^+ (acceptor).

consensus sequence: A DNA or amino acid sequence consisting of the residues that most commonly occur at each position in a set of similar sequences.

conservative substitution: Replacement of an amino acid residue in a polypeptide by another residue with similar properties; for example, substitution of Glu by Asp.

constitutive enzymes: Enzymes required at all times by a cell and present at some constant level; for example, many enzymes of the central metabolic pathways. Sometimes called housekeeping enzymes.

contig: A series of overlapping clones or a continuous sequence defining an uninterrupted section of a chromosome.

contour length: The length of a nucleic acid molecule as measured along its helical axis.

cooperativity: The characteristic of an enzyme or other protein in which binding of the first molecule of a ligand changes the affinity for the second molecule. In positive cooperativity, the affinity for the second ligand molecule increases; in negative cooperativity, it decreases.

cotransport: The simultaneous transport, by a single transporter, of two solutes across a membrane. *See also* antiport; symport; uniport.

coupled reactions: Two chemical reactions that have a common intermediate and thus a means of energy transfer from one to the other.

covalent bond: A chemical bond that involves sharing of electron pairs.

CRISPR/Cas: Bacterial systems that evolved to provide a defense against bacteriophage infection. CRISPR stands for *c*lustered, *r*egularly *i*nterspaced *s*hort *p*alindromic *r*epeats. Cas stands for *C*RISPR-*as*sociated. Engineered CRISPR/Cas systems are used for efficient, targeted genome editing in a wide range of organisms.

cristae: Infoldings of the inner mitochondrial membrane.

CRP: *See* cAMP receptor protein.

cruciform: A secondary structure in double-stranded RNA or DNA in which the double helix is denatured at palindromic repeat sequences in each strand, and each separated strand is paired internally to form opposing hairpin structures. *See also* hairpin.

cryo-electron microscopy (cryo-EM): A technique for determining the structure of proteins or protein complexes; molecules are quick-frozen on a grid in random orientations and visualized by EM. Images of individual molecules are computationally aligned and combined, yielding a three-dimensional map into which a structure can be modeled.

cyclic AMP (cAMP; adenosine 3′,5′-cyclic monophosphate): A second messenger; its formation from ATP in a cell by adenylyl cyclase is stimulated by certain hormones or other molecular signals.

cyclic electron transfer: In chloroplasts, the light-induced transfer of electrons originating from and returning to photosystem I.

cyclic photophosphorylation: ATP synthesis driven by cyclic electron transfer through cytochrome b_6f and photosystem I.

cyclin: One of a family of proteins that activate cyclin-dependent protein kinases and thereby regulate the cell cycle.

cytochrome P-450: A family of heme-containing enzymes, with a characteristic absorption band at 450 nm, that participate in biological hydroxylations with O_2.

cytochromes: Heme proteins serving as electron carriers in respiration, photosynthesis, and other oxidation-reduction reactions.

cytokine: One of a family of small secreted proteins (such as interleukins and interferons) that activate cell division or differentiation by binding to plasma membrane receptors in target cells.

cytokinesis: The final separation of daughter cells following mitosis.

cytoplasm: The portion of a cell's contents outside the nucleus but within the plasma membrane; includes organelles such as mitochondria.

cytoskeleton: The filamentous network that provides structure and organization to the cytoplasm; includes actin filaments, microtubules, and intermediate filaments.

cytosol: The continuous aqueous phase of the cytoplasm, with its dissolved solutes; excludes the organelles such as mitochondria.

d

dalton: Unit of atomic or molecular weight; 1 dalton (Da) is the weight of a hydrogen atom (1.66×10^{-24} g).

dark reactions: *See* carbon-assimilation reactions.

deamination: The enzymatic removal of amino groups from biomolecules such as amino acids or nucleotides.

degenerate code: A code in which a single element in one language is specified by more than one element in a second language.

dehydrogenases: Enzymes that catalyze the removal of pairs of hydrogen atoms from substrates, often with NAD as a coenzyme.

deletion mutation: A mutation resulting from deletion of one or more nucleotides from a gene or chromosome.

ΔG: *See* free-energy change.

$\Delta G^\ddagger$: *See* activation energy.

ΔG°: *See* standard free-energy change.

$\Delta G'^\circ$: *See* biochemical standard free-energy change.

ΔG_B: *See* binding energy.

ΔG_p: *See* phosphorylation potential.

denaturation: Partial or complete unfolding of the specific native conformation of a polypeptide chain, protein, or nucleic acid such that the function of the molecule is lost.

denatured protein: A protein that has lost enough of its native conformation by exposure to a destabilizing agent such as heat or detergent that its function is lost.

de novo pathway: A pathway for the synthesis of a biomolecule, such as a nucleotide, from simple precursors; as distinct from a salvage pathway.

deoxyribonucleic acid: *See* DNA.

deoxyribonucleotides: Nucleotides containing 2-deoxy-D-ribose as the pentose component.

desaturases: Enzymes that catalyze the introduction of double bonds into the hydrocarbon portion of fatty acids.

desensitization: A universal process by which sensory mechanisms cease to respond after prolonged exposure to the specific stimulus they detect.

desolvation: In aqueous solution, the release of bound water surrounding a solute.

diabetes mellitus: A group of metabolic diseases with symptoms that result from a deficiency in insulin production or responsiveness; characterized by an inability to transport glucose from the blood into cells at normal glucose concentrations.

dialysis: Removal of small molecules from a solution of a macromolecule by their diffusion through a semipermeable membrane into a suitably buffered solution.

dideoxy sequencing: *See* Sanger sequencing.

differential centrifugation: Separation of cell organelles or other particles of different size by their different rates of sedimentation in a centrifugal field.

differentiation: Specialization of cell structure and function during growth and development.

diffusion: Net movement of molecules in the direction of lower concentration.

digestion: Enzymatic hydrolysis of major nutrients in the gastrointestinal system to yield their simpler components.

diploid: Having two sets of genetic information; describes a cell with two chromosomes of each type. *Compare* haploid.

disaccharide: A carbohydrate consisting of two covalently joined monosaccharide units.

dissociation constant (K_d): An equilibrium constant for the dissociation of a complex of two or more biomolecules into its components; for example, dissociation of a substrate from an enzyme.

disulfide bond: A covalent bond resulting from the oxidative linkage of two Cys residues, from the same or different polypeptide chains, forming a cystine residue.

DNA (deoxyribonucleic acid): A polynucleotide with a specific sequence of deoxyribonucleotide units covalently joined through 3′,5′-phosphodiester bonds; serves as the carrier of genetic information.

DNA chimera: DNA containing genetic information derived from two different species.

DNA chip: An informal term for a DNA microarray, referring to the small size of typical microarrays.

DNA cloning: *See* cloning.

DNA library: A collection of cloned DNA fragments.

DNA ligases: Enzymes that create a phosphodiester bond between the 3′ end of one DNA segment and the 5′ end of another.

DNA looping: The interaction of proteins bound at distant sites on a DNA molecule so that the intervening DNA forms a loop.

DNA microarray: A collection of DNA sequences immobilized on a solid surface, with individual sequences laid out in patterned arrays that can be probed by hybridization.

DNA polymerases: Enzymes that catalyze template-dependent synthesis of DNA from its deoxyribonucleoside 5′-triphosphate precursors. The bacterium *Escherichia coli* has five DNA polymerases, numbered I through V; eukaryotes have a larger number.

DNA supercoiling: The coiling of DNA upon itself, generally as a result of bending, underwinding, or overwinding of the DNA helix.

DNA transposition: *See* transposition.

domain: A distinct structural unit of a polypeptide; domains may have separate functions and may fold as independent, compact units.

double helix: The natural coiled conformation of two complementary, antiparallel DNA chains.

double-reciprocal plot: A plot of $1/V_0$ versus $1/[S]$, which allows a more accurate determination of V_{max} and K_m than a plot of V_0 versus [S]; also called the Lineweaver-Burk plot.

e

***E*°:** *See* standard reduction potential.

***E*′°:** Standard transformed reduction potential. *See* standard reduction potential.

ECM: *See* extracellular matrix.

eicosanoid: Any of several classes of hydrophobic signaling molecules derived from the lipid arachidonate, including prostaglandins, thromboxanes, and leukotrienes, that regulate physiological responses in humans such as inflammation, blood pressure, and fever.

electrochemical gradient: The resultant of the gradients of concentration and of electric charge of an ion across a membrane; the driving force for oxidative phosphorylation and photophosphorylation.

electrochemical potential: The energy required to maintain a separation of charge and of concentration across a membrane.

electrogenic: Contributing to an electrical potential across a membrane.

electron acceptor: A substance that receives electrons in an oxidation-reduction reaction.

electron carrier: A protein, such as a flavoprotein or a cytochrome, that can reversibly gain and lose electrons; functions in the transfer of electrons from organic nutrients to oxygen or some other terminal acceptor.

electron donor: A substance that donates electrons in an oxidation-reduction reaction.

electron transfer: Movement of electrons from electron donor to electron acceptor; especially, from substrates to oxygen via the carriers of the respiratory (electron-transfer) chain.

electron-transfer flavoprotein (ETF): Flavoprotein that carries electrons from fatty acid β-oxidation to the mitochondrial electron transfer chain.

electrophile: An electron-deficient group with a strong tendency to accept electrons from an electron-rich group (nucleophile).

electrophoresis: Movement of charged solutes in response to an electrical field; often used to separate mixtures of ions, proteins, or nucleic acids.

ELISA: *See* enzyme-linked immunosorbent assay.

elongation factors: (1) Proteins that function in the elongation phase of eukaryotic transcription. (2) Specific proteins required in the elongation of polypeptide chains by ribosomes.

eluate: The effluent from a chromatographic column.

enantiomers: Stereoisomers that are nonsuperposable mirror images of each other.

endergonic reaction: A chemical reaction that consumes energy (i.e., for which ΔG is positive).

endocannabinoids: Endogenous substances capable of binding to and functionally activating cannabinoid receptors.

endocrine: Pertaining to cellular secretions that enter the bloodstream and have their effects on distant tissues.

endocytosis: The uptake of extracellular material by its inclusion in a vesicle (endosome) formed by invagination of the plasma membrane.

endonucleases: Enzymes that hydrolyze the interior phosphodiester bonds of a nucleic acid—that is, act at bonds other than the terminal bonds.

endoplasmic reticulum: An extensive system of double membranes in the cytoplasm of eukaryotic cells; it encloses secretory channels and is often studded with ribosomes (rough endoplasmic reticulum).

endothermic reaction: A chemical reaction that takes up heat (i.e., for which ΔH is positive).

end-product inhibition: *See* feedback inhibition.

energy transduction: The conversion of energy from one form to another.

enhancers: DNA sequences that facilitate the expression of a given gene; may be located a few hundred, or even thousand, base pairs away from the gene.

enthalpy (H): The heat content of a system.

enthalpy change (ΔH): For a reaction, approximately equal to the difference between the energy used to break bonds and the energy gained by formation of new bonds.

entropy (S): The extent of randomness or disorder in a system.

enzyme: A biomolecule, either protein or RNA, that catalyzes a specific chemical reaction. It does not affect the equilibrium of the catalyzed reaction; it enhances the rate of the reaction by providing a reaction path with a lower activation energy.

enzyme cascade: A series of reactions, often involved in regulatory events, in which one enzyme activates another (often by phosphorylation), which activates a third, and so on. The effect of a catalyst activating a catalyst is a large amplification of the signal that initiated the cascade. *See also* regulatory cascade.

enzyme-linked immunosorbent assay (ELISA): A sensitive immunoassay that uses an enzyme linked to an antibody or antigen to detect a specific protein.

epigenetic: Describes any inherited characteristic of a living organism that is acquired by means that do not involve the nucleotide sequence of the parental chromosomes; for example, covalent modifications of histones.

epimerases: Enzymes that catalyze the reversible interconversion of two epimers.

epimers: Two stereoisomers differing in configuration at one asymmetric center in a compound having two or more asymmetric centers.

epithelial cell: Any cell that forms part of the outer covering of an organism or organ.

epitope: An antigenic determinant; the particular chemical group or groups in a macromolecule (antigen) to which a given antibody binds.

epitope tag: A protein sequence or domain bound by a well-characterized antibody.

equilibrium: The state of a system in which no further net change is occurring; the free energy is at a minimum.

equilibrium constant (K_{eq}): A constant, characteristic for each chemical reaction, that relates the specific concentrations of all reactants and products at equilibrium at a given temperature and pressure.

erythrocyte: A cell containing large amounts of hemoglobin and specialized for oxygen transport, but without a nucleus or mitochondria; a red blood cell.

essential amino acids: Amino acids that cannot be synthesized by humans and must be obtained from the diet.

essential fatty acids: The group of polyunsaturated fatty acids produced by plants, but not by humans; required in the human diet.

ETF: *See* electron-transferring flavoprotein.

ethanol fermentation: The anaerobic conversion of glucose to ethanol via glycolysis; also called alcohol fermentation. *See also* fermentation.

euchromatin: The regions of interphase chromosomes that are more open (less condensed), where genes are being actively expressed. *Compare* heterochromatin.

eukaryotes: Members of Eukarya, one of the three domains of living organisms; unicellular or multicellular organisms with cells having a membrane-bounded nucleus, multiple chromosomes, and internal organelles.

exchange factors: Enzymes that catalyze the exchange of histone variants within eukaryotic nucleosomes.

excited state: An energy-rich state of an atom or molecule, produced by absorption of light energy; as distinct from ground state.

exergonic reaction: A chemical reaction that proceeds with the release of free energy (i.e., for which ΔG is negative).

exocytosis: The fusion of an intracellular vesicle with the plasma membrane, releasing the vesicle contents to the extracellular space.

exon: The segment of a eukaryotic gene that encodes a portion of the final product of the gene; a segment of RNA that remains after posttranscriptional processing and is transcribed into a protein or incorporated into the structure of an RNA. *See also* intron.

exonucleases: Enzymes that hydrolyze only those phosphodiester bonds that are in the terminal positions of a nucleic acid.

exosome: In eukaryotes, a large protein complex involved in RNA degradation that is composed of a barrel-like assembly of proteins through which RNA is fed into a nuclease.

exothermic reaction: A chemical reaction that releases heat (i.e., for which ΔH is negative).

expression vector: A vector incorporating sequences that allow the transcription and translation of a cloned gene. *See* vector.

extracellular matrix (ECM): An interwoven combination of glycosaminoglycans, proteoglycans, and proteins, just outside the plasma membrane, that provides cell anchorage, positional recognition, and traction during cell migration.

extrahepatic: Describes all tissues outside the liver; implies the centrality of the liver in metabolism.

f

FAD (flavin adenine dinucleotide): The coenzyme of some oxidation-reduction enzymes; contains riboflavin.

F_1 ATPase: The multiprotein subunit of ATP synthase that has the ATP-synthesizing catalytic sites. It interacts with the F_o subunit of ATP synthase, coupling proton movement to ATP synthesis.

fatty acid: A long-chain aliphatic carboxylic acid in natural fats and oils; also a component of membrane phospholipids and glycolipids.

feedback inhibition: Inhibition of an allosteric enzyme at the beginning of a metabolic sequence by the end product of the sequence; also known as end-product inhibition.

fermentation: Energy-yielding anaerobic breakdown of a nutrient molecule, such as glucose, without net oxidation; yields lactate, ethanol, or some other simple product.

ferredoxin: One of a family of small, soluble Fe-S proteins that serve as one-electron carriers between PSI and NADH in photosynthetic organisms.

fibrin: A protein factor that forms the cross-linked fibers in blood clots.

fibrinogen: The inactive precursor protein of fibrin.

fibroblast: A cell of the connective tissue that secretes connective tissue proteins such as collagen.

fibrous proteins: Insoluble proteins that serve a protective or structural role; contain polypeptide chains that generally share a common secondary structure.

first law of thermodynamics: The law stating that, in all processes, the total energy of the universe remains constant.

Fischer projection formulas: A method for representing molecules that shows the configuration of groups around chiral centers; also known as projection formulas.

5′ end: The end of a nucleic acid that lacks a nucleotide bound at the 5′ position of the terminal residue.

flagellum: A cell appendage used in propulsion. Bacterial flagella have a much simpler structure than eukaryotic flagella, which are similar to cilia.

flavin adenine dinucleotide: *See* FAD.

flavin-linked dehydrogenases: Dehydrogenases requiring one of the riboflavin coenzymes, FMN or FAD.

flavin mononucleotide: *See* FMN.

flavin nucleotides: Nucleotide coenzymes (FMN and FAD) containing riboflavin.

flavoprotein: An enzyme containing a flavin nucleotide as a tightly bound prosthetic group.

flippases: Membrane proteins in the ABC transporter family that catalyze movement of phospholipids from the extracellular leaflet (monolayer) to the cytosolic leaflet of a membrane bilayer.

floppases: Membrane proteins in the ABC transporter family that catalyze movement of phospholipids from the cytosolic leaflet (monolayer) to the extracellular leaflet of a membrane bilayer.

fluid mosaic model: The model describing biological membranes as a fluid lipid bilayer with embedded proteins; the bilayer exhibits both structural and functional asymmetry.

fluorescence: Emission of light by excited molecules as they revert to the ground state.

fluorescence recovery after photobleaching: *See* FRAP.

fluorescence resonance energy transfer: *See* FRET.

FMN (flavin mononucleotide): Riboflavin phosphate, a coenzyme of certain oxidation-reduction enzymes.

fold: *See* motif.

footprinting: A technique for identifying the nucleic acid sequence bound by a DNA- or RNA-binding protein.

fraction: A portion of a biological sample that has been subjected to a procedure designed to separate macromolecules based on a property such as solubility, net charge, molecular weight, or function.

fractionation: The process of separating the proteins or other components of a complex molecular mixture into fractions based on differences in properties such as solubility, net charge, molecular weight, or function.

frame shift: A mutation caused by insertion or deletion of one or more paired nucleotides, changing the reading frame of codons during protein synthesis; the polypeptide product has a garbled amino acid sequence beginning at the mutated codon.

FRAP (fluorescence recovery after photobleaching): A technique used to quantify the diffusion of membrane components (lipids or proteins) in the plane of the bilayer.

free energy (*G*): The component of the total energy of a system that can do work at constant temperature and pressure.

free energy of activation ($\Delta G^{\ddagger}$): *See* activation energy.

free-energy change (ΔG): The amount of free energy released (negative ΔG) or absorbed (positive ΔG) in a reaction at constant temperature and pressure.

free radical: *See* radical.

FRET (fluorescence resonance energy transfer): A technique for estimating the distance between two proteins or two domains of a protein by measuring the nonradiative transfer of energy between reporter chromophores when one protein or domain is excited and the fluorescence emitted from the other is quantified.

functional group: The specific atom or group of atoms that confers a particular chemical property on a biomolecule.

furanose: A simple sugar containing the five-membered furan ring.

fusion protein: (1) One of a family of proteins that facilitate membrane fusion. (2) The protein product of a gene created by the fusion of two distinct genes or portions of genes.

futile cycle: *See* substrate cycle.

g

G_i: *See* inhibitory G protein.

G_s: *See* stimulatory G protein.

gametes: Reproductive cells with a haploid gene content; sperm or egg cells.

ganglioside: A sphingolipid containing a complex oligosaccharide as a head group; especially common in nervous tissue.

GAPs: *See* GTPase activator proteins.

GEFs: *See* guanosine nucleotide–exchange factors.

gel filtration: *See* size-exclusion chromatography.

gene: A chromosomal segment that codes for a single functional polypeptide chain or RNA molecule.

gene expression: Transcription, and, in the case of proteins, translation, to yield the product of a gene; a gene is expressed when its biological product is present and active.

gene fusion: The enzymatic attachment of one gene, or part of a gene, to another.

general acid-base catalysis: Catalysis involving proton transfer(s) to or from a molecule other than water.

general transcription factors: Protein factors required for transcription by RNA polymerase II in eukaryotes.

genetic code: The set of triplet code words in DNA (or mRNA) coding for the amino acids of proteins.

genetic engineering: Any process by which genetic material, particularly DNA, is altered by a molecular biologist.

genetic map: A diagram showing the relative sequence and position of specific genes along a chromosome.

genome: All the genetic information encoded in a cell or virus.

genome annotation: The process of assigning actual or likely functions to genes discovered during genomic DNA sequencing projects.

genomic library: A DNA library containing DNA segments that represent all (or most) of the sequences in an organism's genome.

genomics: A science devoted broadly to the understanding of cellular and organism genomes.

genotype: The genetic constitution of an organism, as distinct from its physical characteristics, or phenotype.

geometric isomers: Isomers related by rotation about a double bond; also called cis-trans isomers.

germ-line cell: A type of animal cell that is formed early in embryogenesis and may multiply by mitosis or produce, by meiosis, cells that develop into gametes (egg or sperm cells).

GFP: *See* green fluorescent protein.

globular proteins: Soluble proteins with a globular (somewhat rounded) shape.

glucogenic: Capable of being converted into glucose or glycogen by the process of gluconeogenesis.

gluconeogenesis: The biosynthesis of a carbohydrate from simpler, noncarbohydrate precursors such as oxaloacetate or pyruvate.

GLUT: Designation for a family of membrane proteins that transport glucose.

glycan: A polymer of monosaccharide units joined by glycosidic bonds; polysaccharide.

glyceroneogenesis: The synthesis in adipocytes of glycerol 3-phosphate from pyruvate for use in triacylglycerol synthesis.

glycerophospholipid: An amphipathic lipid with a glycerol backbone; fatty acids are ester-linked to C-1 and C-2 of the glycerol, and a polar alcohol is attached through a phosphodiester linkage to C-3.

glycoconjugate: A compound containing a carbohydrate component bound covalently to a protein or lipid, forming a glycoprotein or glycolipid.

glycogenesis: The process of converting glucose to glycogen.

glycogenin: The protein that both primes the synthesis of new glycogen chains and catalyzes the polymerization of the first few sugar residues of each chain before glycogen synthase continues the extension.

glycogenolysis: The enzymatic breakdown of stored (not dietary) glycogen.

glycolate pathway: The metabolic pathway in photosynthetic organisms that converts glycolate produced during photorespiration into 3-phosphoglycerate.

glycolipid: A lipid containing a carbohydrate group.

glycolysis: The catabolic pathway by which a molecule of glucose is broken down into two molecules of pyruvate. *Compare* aerobic glycolysis.

glycome: The full complement of carbohydrates and carbohydrate-containing molecules of a cell or tissue under a particular set of conditions.

glycomics: The systematic characterization of the glycome.

glycoprotein: A protein containing a carbohydrate group, typically a complex oligosaccharide.

glycosaminoglycan: A heteropolysaccharide of two alternating units: one is either *N*-acetylglucosamine or *N*-acetylgalactosamine; the other is a uronic acid (usually glucuronic acid). Formerly called a mucopolysaccharide.

glycosidic bonds: *See O*-glyosidic bonds.

glycosphingolipid: An amphipathic lipid with a sphingosine backbone to which are attached a long-chain fatty acid and a polar alcohol head group.

glyoxylate cycle: A variant of the citric acid cycle, for the net conversion of acetate into succinate and, eventually, new carbohydrate; present in bacteria and some plant cells.

glyoxysome: A specialized peroxisome containing the enzymes of the glyoxylate cycle; found in cells of germinating seeds.

glypican: A heparan sulfate proteoglycan attached to a membrane through a glycosyl phosphatidylinositol (GPI) anchor.

Golgi complex: A complex membranous organelle of eukaryotic cells; functions in the posttranslational modification of proteins and their secretion from the cell or incorporation into the plasma membrane or organellar membranes.

GPCRs: *See* G protein–coupled receptors.

GPI-anchored protein: A protein held to the outer monolayer of the plasma membrane by its covalent attachment through a short oligosaccharide chain to a phosphatidylinositol molecule in the membrane.

G protein–coupled receptor kinases (GRKs): A family of protein kinases that phosphorylate Ser and Thr residues near the carboxyl terminus of G protein–coupled receptors, initiating their internalization.

G protein–coupled receptors (GPCRs): A large family of membrane receptor proteins with seven transmembrane helical segments, often associating with G proteins to transduce an extracellular signal into a change in cellular metabolism.

G proteins: A large family of GTP-binding proteins that act in intracellular signaling pathways and in membrane trafficking. Active when GTP is bound, they self-inactivate by converting GTP to GDP. Also called guanosine nucleotide–binding proteins.

gram molecular weight: For a compound, the weight in grams that is numerically equal to its molecular weight; the weight of one mole.

grana: Stacks of thylakoids, flattened membranous sacs or disks, in chloroplasts.

green fluorescent protein (GFP): A small protein from a marine organism that produces bright fluorescence in the green region of the visible spectrum. Fusion proteins with GFP are commonly used to determine the subcellular location of the fused protein by fluorescence microscopy.

GRKs: *See* G protein–coupled receptor kinases.

gRNA: *See* guide RNA.

ground state: The normal, stable form of an atom or molecule, as distinct from the excited state.

group transfer potential: A measure of the ability of a compound to donate an activated group (such as a phosphate or acyl group); generally expressed as the standard free energy of hydrolysis.

growth factors: Proteins or other molecules that act from outside a cell to stimulate cell growth and division.

GTPase activator proteins (GAPs): Regulatory proteins that bind activated G proteins and stimulate their intrinsic GTPase activity, speeding their self-inactivation.

guanosine nucleotide–binding proteins: *See* G proteins.

guanosine nucleotide–exchange factors (GEFs): Regulatory proteins that bind to and activate G proteins by stimulating the exchange of bound GDP for GTP.

guide RNA (gRNA): An RNA found in CRISPR systems that has sequences complementary to those in a target DNA such as a phage DNA.

h

hairpin: Secondary structure in single-stranded RNA or DNA, in which complementary parts of a palindromic repeat fold back and pair to form an antiparallel duplex helix closed at one end. *See also* cruciform.

half-life: The time required for the disappearance or decay of one-half of a given component in a system.

haploid: Having a single set of genetic information; describes a cell with one chromosome of each type. *Compare* diploid.

haplotype: A combination of alleles of different genes located sufficiently close together on a chromosome that they tend to be inherited together.

hapten: A small molecule that, when linked to a larger molecule, elicits an immune response.

Haworth perspective formulas: A method for representing cyclic chemical structures so as to define the configuration of each substituent group; commonly used for representing sugars.

helicases: Enzymes that catalyze separation of strands of double-stranded DNA or RNA. Helicases are required for gene replication and expression.

heme: The iron-porphyrin prosthetic group of heme proteins.

heme protein: A protein containing a heme as prosthetic group.

hemoglobin: A heme protein in erythrocytes; functions in oxygen transport.

Henderson-Hasselbalch equation: An equation relating pH, pK_a, and ratio of the concentrations of proton-acceptor (A^-) and proton-donor (HA) species in a solution:

$$\mathrm{pH} = \mathrm{p}K_a + \log\frac{[\mathrm{A}^-]}{[\mathrm{HA}]}.$$

heparan sulfate: A sulfated polymer of alternating *N*-acetylglucosamine and a uronic acid, either glucuronic or iduronic acid; typically found in the extracellular matrix.

hepatocyte: The major cell type of liver tissue.

heterochromatin: The regions of chromosomes that are condensed, in which gene expression is generally suppressed. *Compare* euchromatin.

heteropolysaccharide: A polysaccharide containing more than one type of sugar.

heterotroph: An organism that requires complex nutrient molecules, such as glucose, as a source of energy and carbon.

heterotropic: Describes an allosteric modulator that is distinct from the normal ligand.

heterotropic enzyme: An allosteric enzyme requiring a modulator other than its substrate.

hexose: A simple sugar with a backbone containing six carbon atoms.

hexose monophosphate pathway: *See* pentose phosphate pathway.

high-performance liquid chromatography (HPLC): Chromatographic procedure, often conducted at relatively high pressures using automated equipment, which permits refined and highly reproducible profiles.

Hill coefficient: A measure of cooperative interaction between protein subunits.

Hill reaction: The evolution of oxygen and photoreduction of an artificial electron acceptor by a chloroplast preparation in the absence of carbon dioxide.

histones: The family of basic proteins that associate tightly with DNA in the chromosomes of all eukaryotic cells.

Holliday intermediate: An intermediate in genetic recombination in which two double-stranded DNA molecules are joined by a reciprocal crossover involving one strand of each molecule.

holoenzyme: A catalytically active enzyme, including all necessary subunits, prosthetic groups, and cofactors.

homeobox: A conserved DNA sequence of 180 base pairs that encodes a protein domain found in many proteins with a regulatory role in development.

homeodomain: The protein domain encoded by the homeobox; a regulatory unit that determines the segmentation of a body plan.

homeostasis: The maintenance of a dynamic steady state by regulatory mechanisms that compensate for changes in external circumstances.

homeotic genes: Genes that regulate development of the pattern of segments in the *Drosophila* body plan; similar genes are found in most vertebrates.

homologous genetic recombination: Recombination between two DNA molecules of similar sequence, taking place in all cells; occurs during meiosis and mitosis in eukaryotes.

homologous proteins: Proteins having similar sequences and functions in different species; for example, the hemoglobins.

homologs: Genes or proteins that possess a clear sequence and functional relationship to each other.

homopolysaccharide: A polysaccharide made up of one type of monosaccharide unit.

homotropic: Describes an allosteric modulator that is identical to the normal ligand.

homotropic enzyme: An allosteric enzyme that uses its substrate as a modulator.

hormone: A chemical substance, synthesized in small amounts by an endocrine tissue, that is carried in the blood to another tissue, or diffuses to a nearby cell, where it acts as a messenger to regulate the function of the target tissue or organ.

hormone receptor: A protein in, or on the surface of, target cells that binds a specific hormone and initiates the cellular response.

hormone response element (HRE): A short (12 to 20 base pairs) DNA sequence that binds receptors for steroid, retinoid, thyroid, and vitamin D hormones, altering expression of the contiguous genes. Each hormone has a consensus sequence preferred by the cognate receptor.

housekeeping genes: Genes that encode products (such as the enzymes of the central energy-yielding pathways) needed by cells at all times; also called constitutive genes because they are expressed under all conditions.

HPLC: *See* high-performance liquid chromatography.

HRE: *See* hormone response element.

hyaluronan: A high molecular weight, acidic polysaccharide typically composed of the alternating disaccharide GlcUA(β1→3)GlcNAc; major component of the extracellular matrix, forming larger complexes (proteoglycans) with proteins and other acidic polysaccharides. Also called hyaluronic acid.

hybridoma: Stable, antibody-producing cell lines that grow well in tissue culture; created by fusing an antibody-producing B lymphocyte with a myeloma cell.

hydrogen bond: A weak electrostatic attraction between one electronegative atom (such as oxygen or nitrogen) and a hydrogen atom covalently linked to a second electronegative atom.

hydrolases: Enzymes (e.g., proteases, lipases, phosphatases, nucleases) that catalyze hydrolysis reactions.

hydrolysis: Cleavage of a bond, such as an anhydride or peptide bond, by addition of the elements of water, yielding two or more products.

hydronium ion: The hydrated hydrogen ion (H_3O^+).

hydropathy index: A scale that expresses the relative hydrophobic and hydrophilic tendencies of a chemical group.

hydrophilic: Polar or charged; describes molecules or groups that associate with (dissolve easily in) water.

hydrophobic: Nonpolar; describes molecules or groups that are insoluble in water.

hydrophobic effect: The aggregation of nonpolar molecules in aqueous solution, excluding water molecules; caused largely by an entropic effect related to the hydrogen-bonding structure of the surrounding water.

hyperchromic effect: The large increase in light absorption at 260 nm as a double-helical DNA unwinds (melts).

hypoxia: The metabolic condition in which the supply of oxygen is severely limited.

i

Ig: *See* immunoglobulin.

immune response: The capacity of a vertebrate to generate antibodies to an antigen, a macromolecule foreign to the organism.

immunoblotting: A technique using antibodies to detect the presence of a protein in a biological sample after the proteins have been separated by gel electrophoresis, transferred to a membrane, and immobilized; also called Western blotting.

immunoglobulin (Ig): An antibody protein generated against, and capable of binding specifically to, an antigen.

induced fit: An enzyme conformation change in response to substrate binding that renders the enzyme catalytically active; also denotes a conformation change in any macromolecule in response to ligand binding, such that the binding site better conforms to the shape of the ligand.

inducer: A signal molecule that, when bound to a regulatory protein, increases the expression of a given gene.

induction: An increase in the expression of a gene in response to a change in the activity of a regulatory protein.

informational macromolecules: Biomolecules containing information in the form of specific sequences of different monomers; for example, many proteins, lipids, polysaccharides, and nucleic acids.

inhibitory G protein (G_i): A trimeric GTP-binding protein that, when activated by an associated plasma membrane receptor, inhibits a neighboring membrane enzyme such as adenylyl cyclase. *Compare* stimulatory G protein (G_s).

initiation codon: AUG (sometimes GUG or, more rarely, UUG in bacteria and archaea); codes for the first amino acid in a polypeptide sequence: *N*-formylmethionine in bacteria; methionine in archaea and eukaryotes.

initiation complex: A complex of a ribosome with an mRNA and the initiating Met-tRNA^{Met} or fMet-tRNA^{fMet}, ready for the elongation steps.

inorganic pyrophosphatase: An enzyme that hydrolyzes a molecule of inorganic pyrophosphate to yield two molecules of (ortho) phosphate; also known as pyrophosphatase.

insertion mutation: A mutation caused by insertion of one or more extra bases, or a mutagen, between successive bases in DNA.

insertion sequence: Specific base sequences at either end of a transposable segment of DNA.

in silico: "In silicon"; that is, by computer simulation.

in situ: "In position"; that is, in its natural position or location.

integral proteins: Proteins firmly bound to a membrane by interactions resulting from the hydrophobic effect; as distinct from peripheral proteins.

integrin: One of a large family of heterodimeric transmembrane proteins that mediate adhesion of cells to other cells or to the extracellular matrix.

intercalation: Insertion between stacked aromatic or planar rings; for example, insertion of a planar molecule between two successive bases in a nucleic acid.

intermediary metabolism: In cells, the enzyme-catalyzed reactions that extract chemical energy from nutrient molecules and use it to synthesize and assemble cell components.

intrinsically disordered proteins: Proteins, or segments of proteins, that lack a definable three-dimensional structure in solution. In some cases folding can be dictated by binding partners.

intron: A sequence of nucleotides in a gene that is transcribed but removed from the RNA transcript before translation; also called intervening sequence. *See also* exon.

in vitro: "In glass"; that is, in the test tube.

in vivo: "In life"; that is, in the living cell or organism.

ion channels: Integral proteins that provide for the regulated transport of a specific ion, or ions, across a membrane.

ion-exchange chromatography: A process for separating complex mixtures of ionic compounds by many repeated partitionings between a flowing (mobile) phase and a stationary phase consisting of a polymeric resin that contains fixed charged groups.

ionizing radiation: A type of radiation, such as x-rays, that causes loss of electrons from some organic molecules, thus making them more reactive.

ionophore: A compound that binds one or more metal ions and is capable of diffusing across a membrane, carrying the bound ion.

ionotropic: Describes a membrane receptor that acts as a ligand-gated ion channel. *Compare* metabotropic.

ion product of water (K_w): The product of the concentrations of H^+ and OH^- in pure water; $K_w = [H^+][OH^-] = 1 \times 10^{-14}$ at 25 °C.

iron-sulfur protein: One of a large family of electron-transfer proteins in which the electron carrier is one or more iron ions associated with two or more sulfur atoms of Cys residues or of inorganic sulfide.

isoelectric focusing: An electrophoretic method for separating macromolecules on the basis of isoelectric pH.

isoelectric pH (isoelectric point, pI): The pH at which a solute has no net electric charge and thus does not move in an electric field.

isoenzymes: *See* isozymes.

isomerases: Enzymes that catalyze the transformation of compounds into their positional isomers.

isomers: Any two molecules with the same molecular formula but a different arrangement of molecular groups.

isoprene: The hydrocarbon 2-methyl-1,3-butadiene, a recurring structural unit of terpenoids.

isoprenoid: Any of a large number of natural products synthesized by enzymatic polymerization of two or more isoprene units; also called terpenoid.

isozymes: Multiple forms of an enzyme that catalyze the same reaction but differ in amino acid sequence, substrate affinity, V_{max}, and/or regulatory properties; also called isoenzymes.

k

K_a: *See* acid dissociation constant.

K_d: *See* dissociation constant.

K_{eq}: *See* equilibrium constant.

K_m: *See* Michaelis constant.

K_t ($K_{transport}$): *See* transport constant.

K_w: *See* ion product of water.

ketoacidosis: A pathological condition sometimes experienced by people with untreated diabetes in which the ketone bodies acetoacetate and D-β-hydroxybutyrate reach extraordinary levels in tissues, urine, and blood (ketosis), which lowers the blood pH (acidosis).

ketogenic: Yielding acetyl-CoA, a precursor for ketone body formation, as a breakdown product.

ketone bodies: Acetoacetate, D-β-hydroxybutyrate, and acetone; water-soluble fuels normally exported by the liver but overproduced during fasting or in untreated diabetes mellitus.

ketose: A simple monosaccharide in which the carbonyl group is a ketone.

ketosis: A condition in which the concentration of ketone bodies in the blood, tissues, and urine is abnormally high.

kinases: Enzymes that catalyze phosphorylation of certain molecules by ATP.

kinetics: The study of reaction rates.

Krebs cycle: *See* citric acid cycle.

l

lagging strand: The DNA strand that, during replication, must be synthesized in the direction opposite to that in which the replication fork moves.

Lands cycle: The process of remodeling the fatty acyl content of phosphatidylcholine.

law of mass action: The law stating that the rate of any given chemical reaction is proportional to the product of the activities (or concentrations) of the reactants.

leader: A short sequence near the amino terminus of a protein or the 5′ end of an RNA that has a specialized targeting or regulatory function.

leading strand: The DNA strand that, during replication, is synthesized in the same direction in which the replication fork moves.

leaky mutant: A mutant gene that gives rise to a product with a detectable level of biological activity.

leaving group: The departing or displaced molecular group in a unimolecular elimination or bimolecular substitution reaction.

lectin: A protein that binds a carbohydrate, commonly an oligosaccharide, with very high affinity and specificity, mediating cell-cell interactions.

lethal mutation: A mutation that inactivates a biological function essential to the life of the cell or organism.

leucine zipper: A protein structural motif involved in protein-protein interactions in many eukaryotic regulatory proteins; consists of two interacting α helices in which Leu residues at every seventh position are a prominent feature of the interacting surfaces.

leukocyte: A white blood cell; involved in the immune response in mammals.

leukotriene (LT): Any of a class of noncyclic eicosanoid signaling lipids with three conjugated double bonds; they mediate inflammatory responses, including smooth muscle activity.

ligand: A small molecule that binds specifically to a larger one; for example, a hormone is the ligand for its specific protein receptor.

ligases: Enzymes that catalyze condensation reactions in which two atoms are joined, using the energy of ATP or another energy-rich compound.

light-dependent reactions: The reactions of photosynthesis that require light and cannot occur in the dark; also known as light reactions.

linear electron transfer: The light-induced transfer of electrons from water to $NADP^+$ in oxygen-evolving photosynthesis; involves photosystems I and II.

Lineweaver-Burk equation: An algebraic transform of the Michaelis-Menten equation, allowing determination of V_{max} and K_m by extrapolation of [S] to infinity:

$$\frac{1}{V_0} = \frac{K_m}{V_{max}[S]} + \frac{1}{V_{max}}$$

linking number: The number of times one closed circular DNA strand is wound about another; the number of topological links holding the circles together.

lipases: Enzymes that catalyze the hydrolysis of triacylglycerols.

lipid: A small water-insoluble biomolecule generally containing fatty acids, sterols, or isoprenoid compounds.

lipidome: The full complement of lipid-containing molecules in a cell, organ, or tissue under a particular set of conditions.

lipidomics: The systematic characterization of the lipidome.

lipid transfer protein: A family of proteins that transfer membrane lipids between parts of the endomembrane system at contact points.

lipoate (lipoic acid): A vitamin for some microorganisms; an intermediate carrier of hydrogen atoms and acyl groups in α-keto acid dehydrogenases.

lipoprotein: A lipid-protein aggregate that carries water-insoluble lipids in the blood. The protein component alone is an apolipoprotein.

liposome: A small, spherical vesicle composed of a phospholipid bilayer, forming spontaneously when phospholipids are suspended in an aqueous buffer.

lipoxin (LX): One of a class of hydroxylated linear derivatives of arachidonate that act as potent anti-inflammatory agents.

long noncoding RNA (lncRNA): A functional class of RNA, more than 200 nucleotides long, that does not encode protein, but can have roles in chromosome structure and function.

LT: *See* leukotriene.

LX: *See* lipoxin.

lyases: Enzymes that catalyze removal of a group from a molecule to form a double bond, or addition of a group to a double bond.

lymphocytes: A subclass of leukocytes involved in the immune response. *See also* B lymphocyte; T lymphocyte.

lysis: Destruction of a plasma membrane or (in bacteria) cell wall, releasing the cellular contents and killing the cell.

lysophosphatidylcholine acyltransferases: Enzymes that add polyunsaturated fatty acids of various types to lysophosphatidylcholine at C-2.

lysosome: An organelle of eukaryotic cells; contains many hydrolytic enzymes and serves as a degrading and recycling center for unneeded cellular components.

m

macromolecule: A molecule having a molecular weight in the range of a few thousand to many millions.

MAPKs: *M*itogen-*a*ctivated *p*rotein *k*inases that phosphorylate protein substrates on Ser, Thr, or Tyr residues. They function in protein phosphorylation cascades connecting surface receptors such as the insulin receptor to specific gene expression in the nucleus.

mass-action ratio (*Q*): For the reaction $aA + bB \rightleftharpoons cC + dD$, the ratio $[C]^c[D]^d/[A]^a[B]^b$.

mass spectrometry: A set of methods for the accurate assessment of molecular mass of individual molecules or mixtures of molecules. After samples are introduced to a vacuum and ionized, mass is determined by molecular behavior in successive electrical and magnetic fields, separating ions into a spectrum.

matrix: The space enclosed by the inner membrane of the mitochondrion.

MCS: *See* multiple cloning sites.

mechanistic target of rapamycin complex 1: *See* mTORC1.

Mediator: A highly conserved, multisubunit, eukaryotic coactivator complex required for transcription from many RNA polymerase II promoters.

meiosis: A type of cell division in which diploid cells give rise to haploid cells destined to become gametes or spores.

membrane potential (V_m): The difference in electrical potential across a biological membrane, commonly measured by insertion of a microelectrode; typical values range from −25 mV (by convention, the negative sign indicates that the inside is negative relative to the outside) to more than −100 mV across some plant vacuolar membranes.

membrane transport: Movement of a polar solute across a membrane via a specific membrane protein (a transporter).

messenger ribonucleoprotein complex: A supramolecular complex of messenger RNA and associated proteins. Also called mRNP complex.

messenger RNA (mRNA): A class of RNA molecules that are translated by ribosomes to produce proteins.

metabolic control: The mechanisms by which flux through a metabolic pathway is changed to reflect a cell's altered circumstances.

metabolic regulation: The mechanisms by which a cell resists changes in the concentrations of individual metabolites that would otherwise occur when metabolic control mechanisms alter flux through a pathway.

metabolic syndrome: A combination of medical conditions that together predispose to cardiovascular disease and type 2 diabetes; includes high blood pressure, high concentrations of LDL and triacylglycerol in the blood, slightly elevated fasting blood glucose concentration, and obesity.

metabolism: The entire set of enzyme-catalyzed transformations of organic molecules in living cells; the sum of anabolism and catabolism.

metabolite: A chemical intermediate in the enzyme-catalyzed reactions of metabolism.

metabolome: The complete set of small-molecule metabolites (metabolic intermediates, signals, secondary metabolites) present in a given cell or tissue under specific conditions.

metabolomics: The systematic characterization of the metabolome of a cell or tissue.

metabolon: A supramolecular assembly of sequential metabolic enzymes.

metabotropic: Describes a membrane receptor that acts through a second messenger. *Compare* ionotropic.

metalloprotein: A protein with a metal ion as its prosthetic group.

metamerism: Division of the body into segments, as in insects, for example.

micelle: An aggregate of amphipathic molecules in water, with the nonpolar portions in the interior and the polar portions at the exterior surface, exposed to water.

Michaelis constant (K_m): The substrate concentration at which an enzyme-catalyzed reaction proceeds at one-half its maximum velocity.

Michaelis-Menten equation: The equation describing the hyperbolic dependence of the initial reaction velocity, V_0, on substrate concentration, [S], in many enzyme-catalyzed reactions: $V_0 = \dfrac{V_{max}[S]}{K_m + [S]}$.

Michaelis-Menten kinetics: A kinetic pattern in which the initial rate of an enzyme-catalyzed reaction exhibits a hyperbolic dependence on substrate concentration.

microRNA (miRNA): A class of small RNA molecules (20 to 25 nucleotides after processing is complete) involved in gene silencing by inhibiting translation and/or promoting degradation of particular mRNAs.

microsomes: Membranous vesicles formed by fragmentation of the endoplasmic reticulum of eukaryotic cells; recovered by differential centrifugation.

miRNA: *See* microRNA.

mismatch: A base pair in a nucleic acid that cannot form a normal Watson-Crick pair.

mismatch repair: An enzymatic system for repairing base mismatches in DNA.

mitochondrion: An organelle of eukaryotic cells; contains the enzyme systems required for the citric acid cycle, fatty acid oxidation, respiratory electron transfer, and oxidative phosphorylation.

mitogen-activated protein kinases: *See* MAPKs.

mitosis: In eukaryotic cells, the multistep process that results in chromosome replication and cell division.

mixed-function oxidases: Enzymes that catalyze reactions in which two different substrates are oxidized by molecular oxygen simultaneously, but the oxygen atoms do not appear in the oxidized product.

mixed-function oxygenases: Enzymes (e.g., monooxygenases) that catalyze reactions in which two reductants—one generally NADPH, the other the substrate—are oxidized by molecular oxygen, with one oxygen atom incorporated into the product and the other reduced to H_2O.

mixed inhibition: The reversible inhibition pattern resulting when an inhibitor molecule can bind to either the free enzyme or the enzyme-substrate complex (not necessarily with the same affinity).

modulator: A metabolite that, when bound to the allosteric site of an enzyme, alters its kinetic characteristics.

molar solution: One mole of solute dissolved in water to give a total volume of 1,000 mL.

mole: One gram molecular weight of a compound. *See also* Avogadro's number.

monocistronic mRNA: An mRNA that can be translated into only one protein.

monoclonal antibodies: Antibodies produced by a cloned hybridoma cell, which are therefore identical and directed against the same epitope of the antigen.

monosaccharide: A carbohydrate consisting of a single sugar unit.

moonlighting enzymes: Enzymes that play two distinct roles, at least one of which is catalytic; the other may be catalytic, regulatory, or structural.

motif: Any distinct folding pattern for elements of secondary structure, observed in one or more proteins. A motif can be simple or complex, and can represent all or just a small part of a polypeptide chain. Also called a fold or supersecondary structure.

mRNA: *See* messenger RNA.

mRNP complex: *See* messenger ribonucleoprotein complex.

mTORC1 (mechanistic target of rapamycin complex 1): A multiprotein complex of mTOR (mechanistic target of rapamycin) and several regulatory subunits, which together act as a Ser/Thr protein kinase; stimulated by nutrients and energy-sufficient conditions, it triggers cell growth and proliferation.

mucopolysaccharide: *See* glycosaminoglycan.

multidrug transporters: Plasma membrane transporters in the ABC transporter family that expel several commonly used antitumor drugs, thereby interfering with antitumor therapy.

multienzyme system: A group of related enzymes participating in a given metabolic pathway.

multiple cloning site (MCS): A planned DNA sequence that includes recognition sequences for multiple restriction endonucleases in close proximity.

mutarotation: The change in specific rotation of a pyranose or furanose sugar or glycoside that accompanies equilibration of its α- and β-anomeric forms.

mutases: Enzymes that catalyze the transposition of functional groups.

mutation: An inheritable change in the nucleotide sequence of a chromosome.

myocyte: A muscle cell.

myofibril: A unit of thick and thin filaments of muscle fibers.

myokinase: *See* adenylate kinase.

myosin: A contractile protein; the major component of the thick filaments of muscle and other actin-myosin systems.

n

***N*:** Avogadro's number, the number of molecules in a gram molecular weight (a mole) of any compound (6.02×10^{23}).

NAD, NADP (nicotinamide adenine dinucleotide, nicotinamide adenine dinucleotide phosphate): Nicotinamide-containing coenzymes that function as carriers of hydrogen atoms and electrons in some oxidation-reduction reactions.

NADH dehydrogenase: *See* Complex I.

Na^+K^+ ATPase: The electrogenic ATP-driven active transporter in the plasma membrane of most animal cells that pumps three Na^+ outward for every two K^+ moved inward.

native conformation: The biologically active conformation of a macromolecule.

ncRNA: *See* noncoding RNA.

negative cooperativity: A property of some multisubunit enzymes or proteins in which binding of a ligand or substrate to one subunit impairs binding to another subunit.

negative feedback: Regulation of a biochemical pathway in which a reaction product inhibits an earlier step in the pathway.

neuron: A cell of nervous tissue specialized for transmission of a nerve impulse.

neurotransmitter: A low molecular weight compound (usually containing nitrogen) secreted from the axon terminal of a neuron and bound by a specific receptor on the next neuron or on a myocyte; transmits a nerve impulse.

NHEJ: *See* nonhomologous end joining.

nitrogenase complex: A system of enzymes capable of reducing atmospheric nitrogen to ammonia in the presence of ATP.

nitrogen fixation: Conversion of atmospheric nitrogen (N_2) into a reduced, biologically available form by nitrogen-fixing organisms.

NMR: *See* nuclear magnetic resonance spectroscopy.

noncoding RNA (ncRNA): Any RNA that does not encode instructions for a protein product.

nonessential amino acids: Amino acids that can be made by humans from simpler precursors and are thus not required in the diet.

nonheme iron proteins: Proteins, usually acting in oxidation-reduction reactions, that contain iron but no porphyrin groups.

nonhomologous end joining (NHEJ): A process in which a double-strand break in a chromosome is repaired by end-processing and ligation, often creating mutations at the ligation site.

nonpolar: Hydrophobic; describes molecules or groups that are poorly soluble in water.

nonsense codon: A codon that does not specify an amino acid, but signals termination of a polypeptide chain.

nonsense mutation: A mutation that results in premature termination of a polypeptide chain.

nonsense suppressor: A mutation, usually in the gene for a tRNA, that causes an amino acid to be inserted into a polypeptide in response to a termination (nonsense) codon.

nontemplate strand: *See* coding strand.

nuclear magnetic resonance (NMR) spectroscopy: A technique that utilizes certain quantum mechanical properties of atomic nuclei to study the structure and dynamics of the molecules of which the nuclei are a part.

nucleases: Enzymes that hydrolyze the internucleotide (phosphodiester) linkages of nucleic acids.

nucleic acids: Biologically occurring polynucleotides in which the nucleotide residues are linked in a specific sequence by phosphodiester bonds; DNA and RNA.

nucleoid: In bacteria, the nuclear zone that contains the chromosome but has no surrounding membrane.

nucleolus: In eukaryotic cells, a densely staining structure in the nucleus; the site of rRNA synthesis and ribosome formation.

nucleophile: An electron-rich group with a strong tendency to donate electrons to an electron-deficient nucleus (electrophile); the entering reactant in a bimolecular substitution reaction.

nucleoplasm: The portion of a eukaryotic cell's contents that is enclosed by the nuclear membrane.

nucleoside: A compound consisting of a purine or pyrimidine base covalently linked to a pentose.

nucleoside diphosphate kinase: The enzyme that catalyzes reversible transfer of the terminal phosphate of a nucleoside 5′-triphosphate to a nucleoside 5′-diphosphate.

nucleoside diphosphate sugar: A coenzyme-like carrier of a sugar molecule, functioning in the enzymatic synthesis of polysaccharides and sugar derivatives.

nucleoside monophosphate kinase: An enzyme that catalyzes transfer of the terminal phosphate of ATP to a nucleoside 5′-monophosphate. *Compare* adenylate kinase.

nucleosome: In eukaryotes, a structural unit for packaging chromatin; consists of a DNA strand wound around a histone core.

nucleotide: A nucleoside phosphorylated at one of its pentose hydroxyl groups.

nucleus: In eukaryotes, an organelle that contains chromosomes.

o

***O*-glycosidic bonds:** Bonds between a sugar and another molecule (typically an alcohol, purine, pyrimidine, or sugar) through an intervening oxygen. Also called simply glycosidic bonds.

oligomer: A short polymer, usually of amino acids, sugars, or nucleotides; the definition of "short" is somewhat arbitrary, but usually fewer than 50 subunits.

oligomeric protein: A multisubunit protein having two or more polypeptide chains.

oligonucleotide: A short polymer of nucleotides (usually fewer than 50).

oligopeptide: A short polymer of amino acids joined by peptide bonds.

oligosaccharide: Several monosaccharide groups joined by glycosidic bonds.

ω oxidation: An alternative mode of fatty acid oxidation in which the initial oxidation is at the carbon most distant from the carboxyl carbon; as distinct from α oxidation and β oxidation.

oncogene: A cancer-causing gene; any of several mutant genes that cause cells to exhibit rapid, uncontrolled proliferation. *See also* proto-oncogene.

open reading frame (ORF): A group of contiguous, nonoverlapping nucleotide codons in a DNA or RNA molecule that does not include a termination codon.

open system: A system that exchanges matter and energy with its surroundings. *See also* system.

operator: A region of DNA that interacts with a repressor protein to control the expression of a gene or group of genes.

operon: A unit of genetic expression consisting of one or more related genes and the operator and promoter sequences that regulate their transcription.

opsin: The protein portion of the visual pigment, which becomes rhodopsin with addition of the chromophore retinal.

optical activity: The capacity of a substance to rotate the plane of plane-polarized light.

optimum pH: The characteristic pH at which an enzyme has maximal catalytic activity.

orexigenic: Tending to increase appetite and food consumption. *Compare* anorexigenic.

ORF: *See* open reading frame.

organelles: Membrane-bounded structures found in eukaryotic cells; contain enzymes and other components required for specialized cell functions.

origin: The nucleotide sequence or site in DNA at which replication is initiated.

orthologs: Genes or proteins from different species that possess a clear sequence and functional relationship to each other.

osmosis: Bulk flow of water through a semipermeable membrane into another aqueous compartment containing solute at a higher concentration.

osmotic pressure: Pressure generated by the osmotic flow of water through a semipermeable membrane into an aqueous compartment containing solute at a higher concentration.

oxidases: Enzymes that catalyze oxidation reactions in which molecular oxygen serves as the electron acceptor, but neither of the oxygen atoms is incorporated into the product. *Compare* oxygenases.

oxidation: The loss of electrons from a compound.

oxidation-reduction reaction: A reaction in which electrons are transferred from a donor to an acceptor molecule; also called a redox reaction.

oxidative phosphorylation: The enzymatic phosphorylation of ADP to ATP coupled to electron transfer from a substrate to molecular oxygen.

oxidizing agent (oxidant): The acceptor of electrons in an oxidation-reduction reaction.

oxygenases: Enzymes that catalyze reactions in which oxygen atoms are directly incorporated into the product, forming a hydroxyl or carboxyl group. In a monooxygenase reaction, only one oxygen atom is incorporated; the other is reduced to H_2O. In a dioxygenase reaction, both oxygens are incorporated into the product. *Compare* oxidases.

oxygen-evolving center: In green plants, the region of photosystem II with the cofactor Mn_4O_4Ca, in which H_2O is oxidized to O_2. Also called the water-splitting center.

oxygenic photosynthesis: Light-driven ATP and NADPH synthesis in organisms that use water as the electron source, producing O_2. *Compare* photosynthesis.

P

palindrome: A segment of duplex DNA in which the base sequences of the two strands exhibit twofold rotational symmetry about an axis.

paradigm: In biochemistry, an experimental model or example.

paralogs: Genes or proteins present in the same species that possess a clear sequence and functional relationship to each other.

partition coefficient: A constant that expresses the ratio in which a given solute will be partitioned or distributed between two given immiscible liquids at equilibrium.

passive transporter: A membrane protein that increases the rate of movement of a solute across the membrane along its electrochemical gradient without the input of energy.

pathogenic: Disease-causing.

PCR: *See* polymerase chain reaction.

PDB (Protein Data Bank): An international data bank (www.rcsb.org) that archives data describing the three-dimensional structure of nearly all macromolecules for which structures have been published.

pentose: A simple sugar with a backbone containing five carbon atoms.

pentose phosphate pathway: A pathway, present in most organisms, that interconverts hexoses and pentoses and is a source of reducing equivalents (NADPH) and pentoses for biosynthetic processes; it begins with glucose 6-phosphate and includes 6-phosphogluconate as an intermediate. Also called the phosphogluconate pathway and hexose monophosphate pathway.

peptidases: Enzymes that hydrolyze peptide bonds.

peptide: Two or more amino acids covalently joined by peptide bonds.

peptide bond: A substituted amide linkage between the α-amino group of one amino acid and the α-carboxyl group of another, with elimination of the elements of water.

peptidoglycan: A major component of bacterial cell walls; generally consists of parallel heteropolysaccharides cross-linked by short peptides.

peptidyl transferase: The enzyme activity that synthesizes the peptide bonds of proteins; a ribozyme, part of the rRNA of the large ribosomal subunit.

peripheral proteins: Proteins loosely bound to a membrane by hydrogen bonds or electrostatic forces; generally water-soluble once released from the membrane. *Compare* integral proteins.

permeases: *See* transporters.

peroxisome: An organelle of eukaryotic cells; contains peroxide-forming and peroxide-destroying enzymes.

peroxisome proliferator-activated receptor: *See* PPAR.

PG: *See* prostaglandin.

pH: The negative logarithm of the hydrogen ion concentration of an aqueous solution.

phage: *See* bacteriophage.

phenotype: The observable characteristics of an organism.

phosphatases: Enzymes that cleave phosphate esters by hydrolysis, the addition of the elements of water.

phosphodiester linkage: A chemical grouping that contains two alcohols esterified to one molecule of phosphoric acid, which thus serves as a bridge between them.

phosphogluconate pathway: *See* pentose phosphate pathway.

phospholipid: A lipid containing one or more phosphate groups.

phosphoprotein phosphatases: *See* protein phosphatases.

phosphorolysis: Cleavage of a compound with phosphate as the attacking group; analogous to hydrolysis.

phosphorylases: Enzymes that catalyze phosphorolysis.

phosphorylation: Formation of a phosphate derivative of a biomolecule, usually by enzymatic transfer of a phosphoryl group from ATP.

phosphorylation potential (ΔG_p): The actual free-energy change of ATP hydrolysis under the nonstandard conditions prevailing in a cell.

photochemical reaction center: The part of a photosynthetic complex where the energy of an absorbed photon causes charge separation, initiating electron transfer.

photon: The ultimate unit (a quantum) of light energy.

photophosphorylation: The enzymatic formation of ATP from ADP coupled to the light-dependent transfer of electrons in photosynthetic cells.

photoreduction: The light-induced reduction of an electron acceptor in photosynthetic cells.

photorespiration: Oxygen consumption occurring in illuminated temperate-zone plants that is largely due to oxidation of phosphoglycolate.

photosynthesis: The use of light energy to produce carbohydrates from carbon dioxide and a reducing agent such as water. *Compare* oxygenic photosynthesis.

photosynthetic phosphorylation: *See* photophosphorylation.

photosystem: In photosynthetic cells, a functional set of light-absorbing pigments and its reaction center, where the energy of an absorbed photon is transduced into a separation of electric charges.

phototroph: An organism that can use the energy of light to synthesize its own fuels from simple molecules such as carbon dioxide, oxygen, and water; as distinct from a chemotroph.

pI: *See* isoelectric pH.

PIC: *See* preinitiation complex.

pK_a: The negative logarithm of an equilibrium constant.

PKA: *See* cAMP-dependent protein kinase.

plasmalogen: A phospholipid with an alkenyl ether substituent on C-1 of glycerol.

plasma membrane: The exterior membrane enclosing the cytoplasm of a cell.

plasma proteins: The proteins present in blood plasma.

plasmid: An extrachromosomal, independently replicating, small circular DNA molecule; commonly employed in genetic engineering.

plastid: In plants, a self-replicating organelle; may differentiate into a chloroplast or amyloplast.

plastocyanin: A small, soluble, copper-containing electron carrier in the thylakoid lumen. It transfers electrons, one at a time, between cytochrome b_6f and the reaction center P700, alternating between its Cu^+ and Cu^{2+} forms.

platelets: Small, enucleated cells that initiate blood clotting; they arise from bone marrow cells called megakaryocytes. Also known as thrombocytes.

plectonemic: Describes a structure in a molecular polymer that has a net twisting of strands about each other in a simple and regular way.

PLP: *See* pyridoxal phosphate.

polar: Hydrophilic, or "water-loving"; describes molecules or groups that are soluble in water.

polarity: (1) In chemistry, the nonuniform distribution of electrons in a molecule; polar molecules are usually soluble in water. (2) In molecular biology, the distinction between the 5′ and 3′ ends of nucleic acids.

poly(A) site choice: The strand cleavage and addition of a 3′-poly(A) tract at alternative locations within an mRNA transcript to generate different mature mRNAs.

poly(A) tail: A length of adenosine residues added to the 3′ end of many mRNAs in eukaryotes (and sometimes in bacteria).

polycistronic mRNA: A contiguous mRNA with more than two genes that can be translated into proteins.

polyclonal antibodies: A heterogeneous pool of antibodies produced in an animal by different B lymphocytes in response to an antigen. Different antibodies in the pool recognize different parts of the antigen.

polymerase chain reaction (PCR): A repetitive laboratory procedure that results in geometric amplification of a specific DNA sequence.

polymorphic: Describes a protein for which amino acid sequence variants are present in a population of organisms, but the variations do not destroy the protein's function.

polynucleotide: A covalently linked sequence of nucleotides in which the 3′ hydroxyl of the pentose of one nucleotide residue is joined by a phosphodiester bond to the 5′ hydroxyl of the pentose of the next residue.

polypeptide: A long chain of amino acids linked by peptide bonds; the molecular weight is generally less than 10,000.

polyribosome: *See* polysome.

polysaccharide: A linear or branched polymer of monosaccharide units linked by glycosidic bonds.

polysome: A complex of an mRNA molecule and two or more ribosomes; also called a polyribosome.

polyunsaturated fatty acid (PUFA): A fatty acid with more than one double bond, generally nonconjugated.

P/O ratio: The number of moles of ATP formed in oxidative phosphorylation per $\frac{1}{2}O_2$ reduced (thus, per pair of electrons passed to O_2). Experimental values used in this text are 2.5 for passage of electrons from NADH to O_2, and 1.5 for passage of electrons from FADH to O_2.

porphyria: An inherited disease resulting from the lack of one or more enzymes required to synthesize porphyrins.

porphyrin: A complex nitrogenous compound containing four substituted pyrroles covalently joined in a ring; often complexed with a central metal atom.

positive cooperativity: A property of some multisubunit enzymes or proteins in which binding of a ligand or substrate to one subunit facilitates binding to another subunit.

positive-inside rule: The general observation that most plasma membrane proteins are oriented so that most of their positively charged residues (Lys and Arg) are on the cytosolic face.

posttranscriptional processing: The enzymatic processing of the primary RNA transcript to produce functional RNAs, including mRNAs, tRNAs, rRNAs, and many other classes of RNAs.

posttranslational modification: The enzymatic processing of a polypeptide chain after translation from its mRNA.

PPAR (peroxisome proliferator-activated receptor): A family of nuclear transcription factors, activated by lipidic ligands, that alter the expression of specific genes, including those encoding enzymes of lipid synthesis and breakdown.

prebiotic: A selectively fermented, nondigestible food ingredient that supports the growth of health-promoting bacteria.

precursor transcript: The immediate RNA product of transcription before any posttranscriptional processing reactions. Also called primary transcript.

preinitiation complex (PIC): The set of proteins necessary for positioning RNA polymerases at transcription start sites in eukaryotes. For RNA polymerase II, this can include nearly 100 factors including the polymerase, general transcription factors, and Mediator complex.

pre–steady state: In an enzyme-catalyzed reaction, the period preceding establishment of the steady state, often encompassing just the first enzymatic turnover.

primary structure: A description of the covalent backbone of a polymer (macromolecule), including the sequence of monomeric subunits and any interchain and intrachain covalent bonds.

primary transcript: *See* precursor transcript.

primases: Enzymes that catalyze formation of RNA oligonucleotides used as primers by DNA polymerases.

primer: A short oligomer (e.g., of sugars or nucleotides) to which an enzyme adds additional monomeric subunits.

primer terminus: The end of a primer to which monomeric subunits are added.

priming: (1) In protein phosphorylation, the phosphorylation of an amino acid residue that becomes the binding site and point of reference for phosphorylation of other residues in the same protein. (2) In DNA replication, the synthesis of a short oligonucleotide to which DNA polymerases can add additional nucleotides.

primosome: An enzyme complex that synthesizes the primers required for lagging strand DNA synthesis.

probiotic: A live microorganism that, ingested in adequate amounts, confers a health benefit on the host.

processivity: For any enzyme that catalyzes the synthesis of a biological polymer, the property of adding multiple subunits to the polymer without dissociating from the substrate.

prochiral molecule: A symmetric molecule that can react asymmetrically with an enzyme having an asymmetric active site, generating a chiral product.

projection formulas: *See* Fischer projection formulas.

prokaryote: A term used historically to refer to any species in the domains Bacteria and Archaea. The differences between bacteria (formerly "eubacteria") and archaea are sufficiently great that this term is of marginal usefulness. A tendency to use "prokaryote" when referring only to bacteria is common and misleading; "prokaryote" also implies an ancestral relationship to eukaryotes, which is incorrect. We do not use "prokaryote" and "prokaryotic" in this text.

promoter: A DNA sequence at which RNA polymerase may bind, leading to initiation of transcription.

proofreading: The correction of errors in the synthesis of an information-containing biopolymer by removing incorrect monomeric subunits after they have been covalently added to the growing polymer.

prostaglandin (PG): One of a class of polyunsaturated, cyclic eicosanoid lipids that act as paracrine hormones.

prosthetic group: A metal ion or organic compound (other than an amino acid) covalently bound to a protein and essential to its activity.

proteases: Enzymes that catalyze the hydrolytic cleavage of peptide bonds in proteins.

proteasome: A supramolecular assembly of enzyme complexes that function in the degradation of damaged or unneeded cellular proteins.

protein: A macromolecule composed of one or more polypeptide chains, each with a characteristic sequence of amino acids linked by peptide bonds.

Protein Data Bank: *See* PDB.

protein kinase A (PKA): *See* cAMP-dependent protein kinase.

protein kinases: Enzymes that transfer the terminal phosphoryl group of ATP or another nucleoside triphosphate to a Ser, Thr, Tyr, Asp, or His side chain in a target protein, thereby regulating the activity or other properties of that protein.

protein phosphatases: Enzymes that hydrolyze a phosphate ester or anhydride bond on a protein, releasing inorganic phosphate, P_i. Also called phosphoprotein phosphatases.

protein targeting: The process by which newly synthesized proteins are sorted and transported to their proper locations in the cell.

proteoglycan: A hybrid macromolecule consisting of a heteropolysaccharide joined to a polypeptide; the polysaccharide is the major component.

proteome: The full complement of proteins expressed in a given cell, or the complete complement of proteins that can be expressed by a given genome.

proteomics: Broadly, the study of the protein complement of a cell or organism.

proteostasis: The maintenance of a cellular steady-state collection of proteins that are required for cell functions under a given set of conditions.

protomer: A general term describing any repeated unit of one or more stably associated protein subunits in a larger protein structure. In a protomer with multiple subunits, the subunits may be identical or different.

proton acceptor: An anionic compound capable of accepting a proton from a proton donor; that is, a base.

proton donor: The donor of a proton in an acid-base reaction; that is, an acid.

proton-motive force: The electrochemical potential inherent in a transmembrane gradient of H^+ concentration; used in oxidative phosphorylation and photophosphorylation to drive ATP synthesis.

proto-oncogene: A cellular gene, usually encoding a regulatory protein, that can be converted into an oncogene by mutation.

PUFA: *See* polyunsaturated fatty acid.

purine: A nitrogenous heterocyclic base that is a component of nucleotides and nucleic acids; contains fused pyrimidine and imidazole rings.

puromycin: An antibiotic that inhibits polypeptide synthesis by incorporating into a growing polypeptide chain, causing its premature termination.

pyranose: A simple sugar containing the six-membered pyran ring.

pyridine nucleotide: A nucleotide coenzyme containing the pyridine derivative nicotinamide; NAD or NADP.

pyridoxal phosphate (PLP): A coenzyme containing the vitamin pyridoxine (vitamin B_6); functions in amino group transfer reactions.

pyrimidine: A nitrogenous heterocyclic base that is a component of nucleotides and nucleic acids.

pyrimidine dimer: A covalently joined dimer of two adjacent pyrimidine residues in DNA, induced by absorption of UV light; most commonly derived from two adjacent thymines (a thymine dimer).

pyrophosphatase: *See* inorganic pyrophosphatase.

pyrosequencing: A DNA sequencing technology in which each nucleotide addition by DNA polymerase triggers a series of reactions ending in a luciferase-generated flash of light.

q

Q: *See* mass-action ratio.

quantitative PCR (qPCR): A PCR procedure that allows determination of how much of an amplified template was in the original sample; also called real-time PCR.

quantum: The ultimate unit of energy.

quaternary structure: The three-dimensional structure of a multisubunit protein, particularly the manner in which the subunits fit together.

r

racemic mixture (racemate): An equimolar mixture of the D and L stereoisomers of an optically active compound.

radical: An atom or group of atoms possessing an unpaired electron; also called a free radical.

radioactive isotope: An isotopic form of an element with an unstable nucleus that stabilizes itself by emitting ionizing radiation.

radioimmunoassay (RIA): A sensitive, quantitative method for detecting trace amounts of a biomolecule, based on its capacity to displace a radioactive form of the molecule from combination with its specific antibody.

Ras superfamily of G proteins: Small (M_r ~20,000), monomeric guanosine nucleotide–binding proteins that regulate signaling and membrane trafficking pathways; inactive with GDP bound, activated by displacement of the GDP by GTP, then inactivated by their intrinsic GTPase. Also called small G proteins.

rate constant: The proportionality constant that relates the velocity of a chemical reaction to the concentration(s) of the reactant(s).

rate-limiting step: (1) Generally, the step in an enzymatic reaction with the greatest activation energy or with the transition state of highest free energy. (2) The slowest step in a metabolic pathway.

reaction intermediate: Any chemical species in a reaction pathway that has a finite chemical lifetime.

reactive oxygen species (ROS): Highly reactive products of the partial reduction of O_2, including hydrogen peroxide (H_2O_2), superoxide ($^{\bullet}O_2^-$), and hydroxyl free radical ($^{\bullet}OH$); minor byproducts of oxidative phosphorylation.

reading frame: A contiguous, nonoverlapping set of three-nucleotide codons in DNA or RNA.

real-time PCR: *See* quantitative PCR.

receptor Tyr kinase (RTK): A large family of plasma membrane proteins with a ligand-binding site on the extracellular domain, a single transmembrane helix, and a cytoplasmic domain with protein Tyr kinase activity controlled by the extracellular ligand.

recombinant DNA: DNA formed by the joining of genes into new combinations.

recombination: Any enzymatic process by which the linear arrangement of a nucleic acid sequence in a chromosome is altered by cleavage and rejoining.

recombinational DNA repair: Recombinational processes directed at the repair of DNA strand breaks or cross-links, especially at inactivated replication forks.

redox pair: An electron donor and its corresponding oxidized form; for example, NADH and NAD^+.

redox reaction: *See* oxidation-reduction reaction.

reducing agent (reductant): The electron donor in an oxidation-reduction reaction.

reducing end: The end of a polysaccharide that has a terminal sugar with a free anomeric carbon; the terminal residue can act as a reducing sugar.

reducing equivalent: A general term for an electron or an electron equivalent in the form of a hydrogen atom or a hydride ion.

reducing sugar: A sugar in which the carbonyl (anomeric) carbon is not involved in a glycosidic bond and can therefore undergo oxidation.

reduction: The gain of electrons by a compound or ion.

regulator of G protein signaling (RGS): A protein structural domain that stimulates the GTPase activity of heterotrimeric G proteins.

regulatory cascade: A multistep regulatory pathway in which a signal leads to activation of a series of proteins in succession, with each protein in the succession catalytically activating the next, such that the original signal is amplified exponentially. *See also* enzyme cascade.

regulatory enzyme: An enzyme with a regulatory function, through its capacity to undergo a change in catalytic activity by allosteric mechanisms or by covalent modification.

regulatory gene: A gene that gives rise to a product involved in regulation of the expression of another gene; for example, a gene encoding a repressor protein.

regulatory protein: Protein whose function is to regulate the activity of another protein or enzyme by binding to it.

regulatory sequence: A DNA sequence involved in regulating the expression of a gene; for example, a promoter or operator.

regulon: A group of genes or operons that are coordinately regulated, even though some, or all, may be spatially distant in the chromosome or genome.

relaxed DNA: Any DNA that exists in its most stable, unstrained structure, typically the B form under most cellular conditions.

release factors: Protein factors in the cytosol required for the release of a completed polypeptide chain from a ribosome; also known as termination factors.

renaturation: The refolding of an unfolded (denatured) globular protein so as to restore its native structure and function.

replication: Synthesis of daughter nucleic acid molecules identical to the parental nucleic acid.

replication fork: The Y-shaped structure generally found at the point where DNA is being synthesized.

replicative form: Any of the full-length structural forms of a viral chromosome that serve as distinct replication intermediates.

replisome: The multiprotein complex that promotes DNA synthesis at the replication fork.

repressible enzyme: In bacteria, an enzyme for which synthesis is inhibited when its reaction product is readily available to the cell.

repression: A decrease in the expression of a gene in response to a change in the activity of a regulatory protein.

repressor: The protein that binds to the regulatory sequence or operator for a gene, blocking its transcription.

residue: A single unit in a polymer; for example, an amino acid in a polypeptide chain. The term reflects the fact that sugars, nucleotides, and amino acids lose a few atoms (generally the elements of water) when incorporated in their respective polymers.

respirasome: A supercomplex of electron transfer Complexes I, III, and IV in the mitochondrial inner membrane.

respiration: Any metabolic process that leads to the uptake of oxygen and release of CO_2.

respiration-linked phosphorylation: ATP formation from ADP and P_i, driven by electron transfer through a series of membrane-bound carriers, with a proton gradient as the direct source of energy driving rotational catalysis by ATP synthase.

respiratory chain: The electron-transfer chain; a sequence of electron-carrying proteins that transfers electrons from substrates to molecular oxygen in aerobic cells.

response element: A region of DNA, near (upstream from) a gene, bound by specific proteins that influence the rate of transcription of the gene.

restriction endonucleases: Site-specific endonucleases that cleave both strands of DNA at points in or near the specific site recognized by the enzyme; important tools in genetic engineering.

restriction fragment: A segment of double-stranded DNA produced by the action of a restriction endonuclease on a larger DNA.

restriction-modification system: A paired enzyme system, generally in bacteria, that will either cleave (restrict) invading viral DNA at a particular sequence or methylate (modify) one or more nucleotides within the same sequence where it occurs in the host chromosome, so as to avoid chromosome cleavage.

retinal: A 20-carbon isoprene aldehyde derived from carotene, which serves as the light-sensitive component of the visual pigment rhodopsin. Illumination converts 11-*cis*-retinal to all-*trans*-retinal.

retrovirus: An RNA virus containing a reverse transcriptase.

reverse transcriptase: An RNA-directed DNA polymerase of retroviruses; capable of making DNA complementary to an RNA.

reverse transcriptase PCR (RT-PCR): A PCR procedure in which reverse transcriptase is used to convert RNA into cDNA in the first few steps. The cDNA is then amplified by standard PCR or qPCR. When coupled to qPCR, the method can provide a measure of RNA abundance.

reversible inhibition: Inhibition by a molecule that binds reversibly to the enzyme, such that the enzyme activity returns when the inhibitor is no longer present.

reversible terminator sequencing: A DNA sequencing technology in which nucleotide additions are detected and scored by the color of fluorescence displayed when a labeled nucleotide with a removable sequence terminator is added.

R group: (1) Formally, an abbreviation denoting any alkyl group. (2) Occasionally, used in a more general sense to denote virtually any organic substituent (e.g., the R groups of amino acids).

RGS: *See* regulator of G protein signaling.

rhodopsin: The visual pigment, composed of the protein opsin and the chromophore retinal.

RIA: *See* radioimmunoassay.

ribonuclease: A nuclease that catalyzes the hydrolysis of certain internucleotide linkages of RNA.

ribonucleic acid: *See* RNA.

ribonucleoprotein (RNP): Biomolecule with subunits of both RNA and protein. Examples include telomerase, spliceosomes, and ribosomes.

ribonucleotide: A nucleotide containing D-ribose as its pentose component.

ribosomal RNA (rRNA): A class of RNA molecules serving as components of ribosomes.

ribosome: A supramolecular complex of rRNAs and proteins, approximately 18 to 22 nm in diameter; the site of protein synthesis.

ribosome profiling: A technique employing next-generation DNA sequencing of cDNA fragments derived from RNA bound to cellular ribosomes, to determine what mRNAs are being translated at a given moment.

riboswitch: A structured segment of an mRNA that binds to a specific ligand and affects translation or processing of the mRNA.

ribozymes: Ribonucleic acid molecules with catalytic activities; RNA enzymes.

ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco): The enzyme that fixes CO_2 into organic form (3-phosphoglycerate) in organisms (plants and some microorganisms) capable of CO_2 fixation.

Rieske iron-sulfur protein: A type of iron-sulfur protein in which two of the ligands to the central iron ion are His side chains; act in many electron-transfer sequences, including oxidative phosphorylation and photophosphorylation.

RNA (ribonucleic acid): A polyribonucleotide of a specific sequence linked by successive 3′,5′-phosphodiester bonds.

RNA editing: Posttranscriptional modification of an mRNA that can alter the meaning of one or more codons during translation.

RNA polymerase: An enzyme that catalyzes formation of RNA from ribonucleoside 5′-triphosphates, using a strand of DNA or RNA as a template.

RNA recognition motif (RRM): A single-stranded nucleic acid–binding motif consisting of a four-strand antiparallel β sheet with two α helices on one face.

RNA-Seq: A method for determining the relative expression levels of all or selected groups of genes within a genome.

RNA splicing: Removal of introns and joining of exons in a primary transcript. Also called simply splicing.

RNA world hypothesis: A hypothesis that life on Earth originated with molecules like RNA capable of storing and replicating genetic information in addition to catalyzing biochemical reactions.

RNP: *See* ribonucleoprotein.

ROS: *See* reactive oxygen species.

rRNA: *See* ribosomal RNA.

RRM: *See* RNA recognition motif.

RTK: *See* receptor Tyr kinase.

RT-PCR: *See* reverse transcriptase PCR.

rubisco: *See* ribulose 1,5-bisphosphate carboxylase/oxygenase.

S

salvage pathway: A pathway for synthesis of a biomolecule, such as a nucleotide, from intermediates in the degradative pathway for the biomolecule; a recycling pathway, as distinct from a de novo pathway.

Sanger sequencing: A DNA sequencing method based on the use of dideoxynucleoside triphosphates, developed by Frederick Sanger; also called dideoxy sequencing.

sarcomere: A functional and structural unit of the muscle contractile system.

satellite DNA: *See* simple-sequence DNA.

saturated fatty acid: A fatty acid containing a fully saturated alkyl chain.

scaffold proteins: Noncatalytic proteins that nucleate formation of multienzyme complexes by providing two or more specific binding sites for those proteins.

scramblases: Membrane proteins that catalyze movement of phospholipids across the membrane bilayer, leading to uniform distribution of a lipid between the two membrane leaflets (monolayers).

scRNA-seq: *See* single-cell RNA-seq.

secondary metabolism: Pathways that lead to specialized products not found in every living cell.

secondary structure: The local spatial arrangement of the main-chain atoms in a segment of a polymer (polypeptide or polynucleotide) chain.

second law of thermodynamics: The law stating that, in any chemical or physical process, the entropy of the universe tends to increase.

second messenger: An effector molecule synthesized in a cell in response to an external signal (first messenger) such as a hormone.

sedimentation coefficient: A physical constant specifying the rate of sedimentation of a particle in a centrifugal field under specified conditions.

selectins: A large family of membrane proteins that bind oligosaccharides on other cells tightly and specifically and carry signals across the plasma membrane.

SELEX: A method for rapid experimental identification of nucleic acid sequences (usually RNA) that have particular catalytic or ligand-binding properties.

septins: A family of highly conserved GTP-binding proteins that act in processes that involve membrane bending, such as cytokinesis, exocytosis, phagocytosis, and apoptosis.

sequence polymorphisms: Any alterations in genomic sequence (base-pair changes, insertions, deletions, rearrangements) that help distinguish subsets of individuals in a population or distinguish one species from another.

sequencing depth: The number of times, on average, that a given genomic nucleotide is included in sequenced DNA segments.

serine proteases: One of four major classes of proteases, having a reaction mechanism in which an active-site Ser residue acts as a covalent catalyst.

sgRNA: *See* single guide RNA.

Shine-Dalgarno sequence: A sequence in an mRNA that is important for binding bacterial ribosomes.

short tandem repeat (STR): A short (typically 3 to 6 base pairs) DNA sequence, repeated many times in tandem at a particular location in a chromosome.

SH2 domain: A protein domain that binds tightly to a phosphotyrosine residue in certain proteins, such as the receptor Tyr kinases, initiating formation of a multiprotein complex that acts in a signaling pathway.

shuttle vector: A recombinant DNA vector that can be replicated in two or more different host species. *See also* vector.

sickle cell anemia: A human disease characterized by defective hemoglobin molecules in individuals homozygous for a mutant allele coding for the β chain of hemoglobin.

σ: (1) A subunit of the bacterial RNA polymerase that confers specificity for certain promoters; usually designated by a superscript indicating its size (e.g., σ^{70} has a molecular weight of 70,000). (2) *See* superhelical density.

signal sequence: An amino acid sequence, often at the amino terminus, that signals the cellular fate or destination of a newly synthesized protein.

signal transduction: The process by which an extracellular signal (chemical, mechanical, or electrical) is amplified and converted to a cellular response.

silent mutation: A gene mutation that causes no detectable change in the biological characteristics of the gene product.

simple diffusion: Movement of solute molecules across a membrane to a region of lower concentration, unassisted by a protein transporter.

simple protein: A protein yielding only amino acids on hydrolysis.

simple-sequence DNA: Highly repeated, nontranslated segments of DNA in eukaryotic chromosomes; most often associated with the centromeric region. Its function is unknown. Also called satellite DNA.

single cell RNA-Seq (scRNA-Seq): An adaptation of RNA-Seq that is focused on global levels of gene expression within a single cell.

single guide RNA (sgRNA): A combination of gRNA and tracrRNA that allows one RNA to both activate Cas nucleases (particularly Cas9) and target the system to a particular DNA sequence. Parts of the RNA can be engineered to target the system to any desired DNA sequence.

single-molecule real-time (SMRT) sequencing: A DNA sequencing technology in which nucleotide additions are detected as flashes of fluorescent colored light, with sensitivity enhanced so that long DNA molecules (up to 15,000 nucleotides) can be sequenced and the results displayed in real time.

single nucleotide polymorphism (SNP): A genomic base-pair change that helps distinguish one species from another or one subset of individuals in a population.

site-directed mutagenesis: A set of methods used to create specific alterations in the sequence of a gene.

site-specific recombination: A type of genetic recombination that occurs only at specific sequences.

size-exclusion chromatography: A procedure for separation of molecules by size, based on the capacity of porous polymers to exclude solutes above a certain size; also called gel filtration.

small G proteins: *See* Ras superfamily of G proteins.

small nuclear RNA (snRNA): A class of short RNAs, typically 100 to 200 nucleotides long, present in the nucleus; involved in the splicing of eukaryotic mRNAs.

small nucleolar RNA (snoRNA): A class of short RNAs, generally 60 to 300 nucleotides long, that guide modification of rRNAs in the nucleolus.

SMRT sequencing: *See* single-molecule real-time sequencing.

SNP: *See* single nucleotide polymorphism.

snRNA: *See* small nuclear RNA.

snoRNA: *See* small nucleolar RNA.

somatic cells: All body cells except the germ-line cells.

SOS response: In bacteria, a coordinated induction of a variety of genes in response to high levels of DNA damage.

Southern blot: A DNA hybridization procedure in which one or more specific DNA fragments are detected in a larger population by hybridization to a complementary, labeled nucleic acid probe.

specialized pro-resolving mediator (SPM): One of several eicosanoids, derived from essential fatty acids, that promote the resolution phase of the inflammatory response.

specific acid-base catalysis: Acid or base catalysis involving the constituents of water (hydroxide or hydronium ions).

specific activity: The number of micromoles (μmol) of a substrate transformed by an enzyme preparation per minute per milligram of protein at 25 °C; a measure of enzyme purity.

specificity: The ability of an enzyme or receptor to discriminate among competing substrates or ligands.

specific rotation: The rotation, in degrees, of the plane of plane-polarized light (D-line of sodium) by an optically active compound at 25 °C, with a specified concentration and light path.

sphingolipid: An amphipathic lipid with a sphingosine backbone to which are attached a long-chain fatty acid and a polar alcohol.

spliceosome: A complex of RNAs and proteins involved in the splicing of mRNAs in eukaryotic cells.

splicing: *See* RNA splicing.

SPM: *See* specialized pro-resolving mediator.

standard free-energy change ($\Delta G°$): The free-energy change for a reaction occurring under a set of standard conditions: temperature, 298 K; pressure, 1 atm (101.3 kPa); and all solutes at 1 M concentration. $\Delta G'°$ denotes the standard transformed free-energy change at pH 7.0 in 55.5 M water used by biochemists.

standard reduction potential ($E°$): The electromotive force exhibited at an electrode by 1 M concentrations of a reducing agent and its oxidized form at 25 °C; a measure of the relative tendency of the reducing agent to lose electrons. $E'°$ denotes the standard transformed reduction potential at pH 7.0 and 55.5 M water used by biochemists.

statin: Any of a class of drugs used to reduce blood cholesterol in humans; acts by inhibiting the enzyme HMG-CoA reductase, an early step in sterol synthesis.

steady state: A nonequilibrium state of a system through which matter is flowing and in which all components remain at a constant concentration.

stem cells: The common, self-regenerating cells in bone marrow that give rise to differentiated blood cells such as erythrocytes and lymphocytes.

stereoisomers: Compounds that have the same composition and the same order of atomic connections but different molecular arrangements.

sterol: A group of steroid lipids in which the 3 position of the A ring of the steroid nucleus has been modified with a hydroxyl group.

sticky ends: Two DNA ends in the same DNA molecule, or in different molecules, with short overhanging single-stranded segments that are complementary to one another, facilitating ligation of the ends; also known as cohesive ends.

stimulatory G protein (G_s): A trimeric regulatory GTP-binding protein that, when activated by an associated plasma membrane receptor, stimulates a neighboring membrane enzyme such as adenylyl cyclase; its effects oppose those of G_i. *Compare* inhibitory G protein (G_i).

stop codons: *See* termination codons.

STR: *See* short tandem repeat.

stroma: The space and aqueous solution enclosed within the inner membrane of a chloroplast, not including the contents of the thylakoid membranes.

structural gene: A gene coding for a protein or RNA molecule; as distinct from a regulatory gene.

substitution mutation: A mutation caused by replacement of one base by another.

substrate: The specific compound acted upon by an enzyme.

substrate channeling: Movement of the chemical intermediates in a series of enzyme-catalyzed reactions from the active site of one enzyme to that of the next enzyme in the pathway, without leaving the surface of the protein complex that includes the enzymes.

substrate cycle: A cycle of enzyme-catalyzed reactions that results in release of thermal energy by the hydrolysis of ATP; sometimes referred to as a futile cycle.

substrate-level phosphorylation: Phosphorylation of ADP or some other nucleoside 5′-diphosphate coupled to dehydrogenation of an organic substrate; independent of the respiratory chain.

suicide inactivator: A relatively inert molecule that is transformed by an enzyme, at its active site, into a reactive substance that irreversibly inactivates the enzyme.

sulfonylurea drugs: A group of oral medications used in the treatment of type 2 diabetes; act by closing K^+ channels in pancreatic β cells, stimulating insulin secretion.

supercoil: The twisting of a helical (coiled) molecule on itself; a coiled coil.

supercoiled DNA: DNA that twists upon itself because it is under- or overwound (and thereby strained) relative to B-form DNA.

superhelical density (σ): In a helical molecule such as DNA, the number of supercoils (superhelical turns) relative to the number of coils (turns) in the relaxed molecule.

supersecondary structure: *See* motif.

suppressor mutation: A mutation, at a site different from that of a primary mutation, that totally or partially restores a function lost by the primary mutation.

Svedberg (S): A unit of measure of the rate at which a particle sediments in a centrifugal field.

symbionts: Two or more organisms that are mutually interdependent and usually living in physical association.

symport: Cotransport of solutes across a membrane in the same direction.

syndecan: A heparan sulfate proteoglycan with a single transmembrane domain and an extracellular domain bearing three to five chains of heparan sulfate and, in some cases, chondroitin sulfate.

synteny: Conserved gene order along the chromosomes of different species.

synthases: Enzymes that catalyze condensation reactions that do not require nucleoside triphosphate as an energy source.

synthetases: Enzymes that catalyze condensation reactions using ATP or another nucleoside triphosphate as an energy source.

system: An isolated collection of matter; all other matter in the universe apart from the system is called the surroundings.

systems biology: The study of complex biochemical systems, integrating information from genomics, proteomics, and metabolomics.

t

TADs: *See* topologically associating domains.

tag: An extra segment of protein that is fused to a protein of interest by modification of its gene, usually for purposes of purification.

tautomers: Isomers that interconvert rapidly such that they exist in equilibrium.

TCA (tricarboxylic acid) cycle: *See* citric acid cycle.

T cell: *See* T lymphocyte.

telomerase: The ribonucleoprotein supramolecular complex responsible for addition of telomere repeat DNA to chromosome ends in eukaryotes.

telomere: A specialized nucleic acid structure at the ends of linear eukaryotic chromosomes.

template: A macromolecular mold or pattern for the synthesis of an informational macromolecule.

template strand: A strand of nucleic acid used by a polymerase as a template to synthesize a complementary strand, as distinct from the coding strand.

terminal transferase: An enzyme that catalyzes addition of nucleotide residues of a single kind to the 3′ end of DNA chains.

termination codons: UAA, UAG, and UGA; in protein synthesis, these codons signal termination of a polypeptide chain. Also known as stop codons.

termination factors: *See* release factors.

termination sequence: A DNA sequence, at the end of a transcriptional unit, that signals the end of transcription.

tertiary structure: The three-dimensional conformation of a polymer in its native, folded state.

tetrahydrobiopterin: The reduced coenzyme form of biopterin.

tetrahydrofolate: The reduced, active coenzyme form of the vitamin folate.

thermogenesis: The biological generation of heat by muscle activity (shivering), uncoupled oxidative phosphorylation, or the operation of substrate (futile) cycles.

thermogenin: *See* uncoupling protein 1.

thiamine pyrophosphate (TPP): The active coenzyme form of vitamin B_1; involved in aldehyde transfer reactions.

thiazolidinediones: A class of medications used in the treatment of type 2 diabetes; act to reduce circulating fatty acids and increase sensitivity to insulin. Also known as glitazones.

thioester: An ester of a carboxylic acid with a thiol or mercaptan.

thioredoxin: A small, ubiquitous protein with a pair of Cys residues that participate in redox reactions, alternating between their —SH and —S—S— forms. One role is to maintain the sulfhydryl residues of key proteins in their reduced state.

3′ end: The end of a nucleic acid that lacks a nucleotide bound at the 3′ position of the terminal residue.

thrombocytes: *See* platelets.

thromboxane (TX): Any of a class of eicosanoid lipids with a six-membered ether-containing ring; involved in platelet aggregation during blood clotting.

thylakoid: A closed, continuous system of flattened disks, formed by the pigment-bearing internal membranes of chloroplasts.

thymine dimer: *See* pyrimidine dimer.

tissue culture: A method by which cells derived from multicellular organisms are grown in liquid media.

titration curve: A plot of pH versus the equivalents of base added during titration of an acid.

T lymphocyte (T cell): One of a class of blood cells (lymphocytes) of thymic origin, involved in cell-mediated immune reactions.

tocopherol: Any of several forms of vitamin E.

topoisomerases: Enzymes that introduce positive or negative supercoils in closed, circular duplex DNA.

topoisomers: Different forms of a covalently closed, circular DNA molecule that differ only in linking number.

topologically associating domains (TADs): Large DNA loops within chromosomes, constrained at the base and encompassing 800,000 or more base pairs of DNA; found in both transcriptionally active and inactive chromosomal regions.

topology: The study of the properties of an object that do not change under continuous deformations such as twisting or bending.

topology diagram: A structural representation in which the connections between elements of secondary structure are depicted in two dimensions.

TPP: *See* thiamine pyrophosphate.

trace element: A chemical element required by an organism in only trace amounts.

trans-activating CRISPR RNA (tracrRNA): A bacterially encoded RNA required for the activation and function of the relatively simple CRISPR/Cas system in the human pathogen *Streptococcus pyogenes*.

transaminases: *See* aminotransferases.

transamination: Enzymatic transfer of an amino group from an α-amino acid to an α-keto acid.

transcription: The enzymatic process whereby the genetic information contained in one strand of DNA is used to specify a complementary sequence of bases in an mRNA.

transcriptional control: Regulation of the synthesis of a protein by regulation of the formation of its mRNA.

transcription factor: A protein that affects the regulation and transcription initiation of a gene by binding to a regulatory sequence near or within the gene and interacting with RNA polymerase and/or other transcription factors.

transcriptome: The entire complement of RNA transcripts present in a given cell or tissue under specific conditions.

transcriptomics: A discipline focused on the study of gene expression on a genomic scale, often following increases and decreases in transcription of various genes under different conditions.

transduction: (1) Generally, the conversion of energy or information from one form to another. (2) The transfer of genetic information from one cell to another by means of a viral vector.

transfer RNA (tRNA): A class of RNA molecules (M_r 25,000 to 30,000), each of which combines covalently with a specific amino acid as the first step in protein synthesis.

transformation: Introduction of an exogenous DNA into a cell, causing the cell to acquire a new phenotype.

transgenic: Describes an organism that has genes from another organism incorporated in its genome as a result of recombinant DNA procedures.

transition state: An activated form of a molecule in which the molecule has undergone a partial chemical reaction; the highest point on the reaction coordinate.

transition-state analog: A stable molecule that resembles the transition state of a particular reaction and therefore binds the enzyme that catalyzes the reaction more tightly than does the substrate in the enzyme-substrate complex.

translation: The process in which the genetic information in an mRNA molecule specifies the sequence of amino acids during protein synthesis.

translational control: Regulation of the synthesis of a protein by regulation of the rate of its translation on the ribosome.

translational frameshifting: A programmed change in the reading frame during translation of an mRNA on a ribosome, occurring by any of several mechanisms.

translational repressor: A repressor that binds to an mRNA, blocking translation.

translocase: An enzyme that causes movement, such as movement of a ribosome along an mRNA.

transpiration: Passage of water from the roots of a plant to the atmosphere via the vascular system and the stomata of leaves.

transport constant (K_t; $K_{\text{transport}}$): A kinetic parameter for a membrane transporter, analogous to the Michaelis constant, K_m, for an enzymatic reaction. The rate of substrate uptake is half-maximal when the substrate concentration equals K_t.

transporters: Proteins that span a membrane and transport specific nutrients, metabolites, ions, or proteins across the membrane; sometimes called permeases.

transposition: Movement of a gene or set of genes from one site in the genome to another. Also called DNA transposition.

transposon (transposable element): A segment of DNA that can move from one position in the genome to another.

triacylglycerol: An ester of glycerol with three molecules of fatty acid; also called a triglyceride or neutral fat.

tricarboxylic acid (TCA) cycle: *See* citric acid cycle.

trimeric G proteins: Members of the G protein family with three subunits; function in a variety of signaling pathways. They are inactive with GDP bound, activated by associated receptors as the GDP is displaced by GTP, then inactivated by their intrinsic GTPase activity.

triose: A simple sugar with a backbone containing three carbon atoms.

tRNA: *See* transfer RNA.

tropic hormones (tropins): Peptide hormones that stimulate a specific target gland to secrete its hormone; for example, thyrotropin produced by the pituitary stimulates secretion of thyroxine by the thyroid.

t-SNAREs: Protein receptors in a targeted membrane (typically the plasma membrane) that bind to v-SNAREs in the membrane of a secretory vesicle, mediating fusion of the vesicle and target membranes.

tumor suppressor gene: One of a class of genes that encode proteins that normally regulate the cell cycle by suppressing cell division. Mutation of one copy of the gene is usually without effect, but when both copies are defective, the cell continues dividing without limitation, producing a tumor.

turnover number: The number of times an enzyme molecule transforms a substrate molecule per unit time, under conditions giving maximal activity at saturating substrate concentrations.

TX: *See* thromboxane.

type 2 diabetes mellitus: A metabolic disorder characterized by insulin resistance and poorly regulated blood glucose level; also known as adult-onset diabetes or noninsulin-dependent diabetes (NIDD).

u

ubiquitin: A small, highly conserved eukaryotic protein that targets an intracellular protein for degradation by proteasomes. Several ubiquitin molecules are covalently attached in tandem to a Lys residue of the target protein by a ubiquitinating enzyme.

ultraviolet (UV) radiation: Electromagnetic radiation in the region of 200 to 400 nm.

uncompetitive inhibition: The reversible inhibition pattern resulting when an inhibitor molecule can bind to the enzyme-substrate complex but not to the free enzyme.

uncoupling protein 1 (UCP1): A protein of the inner mitochondrial membrane in brown and beige adipose tissue that allows transmembrane movement of protons, short-circuiting the normal use of protons to drive ATP synthesis and dissipating the energy of substrate oxidation as heat. Also called thermogenin.

uniport: A transport system that carries only one solute, as distinct from cotransport.

unsaturated fatty acid: A fatty acid containing one or more double bonds.

urea cycle: A cyclic metabolic pathway in vertebrate liver that synthesizes urea from amino groups and carbon dioxide.

ureotelic: Excreting excess nitrogen in the form of urea.

uricotelic: Excreting excess nitrogen in the form of urate (uric acid).

v

V_0: Initial velocity, the initial rate of a reaction.

V_m: *See* membrane potential.

V_{max}: The maximum velocity of an enzymatic reaction when the binding site is saturated with substrate.

van der Waals interactions: Weak intermolecular forces between molecules as a result of each inducing polarization in the other.

vector: A DNA molecule known to replicate autonomously in a host cell, to which a segment of DNA may be spliced to allow its replication in a cell; for example, a plasmid or an artificial chromosome.

vectorial: Describes an enzymatic reaction or transport process in which the protein has a specific orientation in a biological membrane such that the substrate is moved from one side of the membrane to the other as it is converted into product.

vectorial metabolism: Metabolic transformations in which the location (not the chemical composition) of a substrate changes relative to the plasma membrane or organellar membrane; for example, the action of transporters and the proton pumps of oxidative phosphorylation and photophosphorylation.

vesicle: A small, spherical, membrane-bounded particle with an internal aqueous compartment that contains components such as hormones or neurotransmitters to be moved within or out of a cell.

viral vector: A viral DNA altered so that it can act as a vector for recombinant DNA.

virion: A virus particle.

virus: A self-replicating, infectious, nucleic acid–protein complex that requires an intact host cell for its replication; its genome is DNA or RNA.

vitamin: An organic substance required in small quantities in the diet of some species; generally functions as a component of a coenzyme.

v-SNAREs: Protein receptors in the membrane of a secretory vesicle that bind to t-SNAREs in a targeted membrane (typically the plasma membrane) and mediate fusion of the vesicle and target membranes.

w

water-splitting center: *See* oxygen-evolving center.

Western blotting: *See* immunoblotting.

white adipose tissue (WAT): Nonthermogenic adipose tissue rich in triacylglycerols, stored and mobilized in response to hormonal signals. Transfer of electrons in the respiratory chain of WAT mitochondria is tightly coupled to ATP synthesis. *Compare* beige adipose tissue; brown adipose tissue.

wild type: The normal (unmutated) genotype or phenotype.

wobble: The relatively loose base pairing between the base at the 3′ end of a codon and the complementary base at the 5′ end of the anticodon.

x

x-ray crystallography: The analysis of x-ray diffraction patterns of a crystalline compound, used to determine the molecule's three-dimensional structure.

z

zinc finger: A specialized protein motif of some DNA-binding proteins, involved in DNA recognition; characterized by a single atom of zinc coordinated to four Cys residues or to two His and two Cys residues.

Z scheme: In oxygenic photosynthesis, the path of electrons from water through photosystem II and the cytochrome b_6f complex to photosystem I and finally to NADPH. When the sequence of electron carriers is plotted against their reduction potentials, the path of electrons looks like a sideways Z.

zwitterion: A dipolar ion with spatially separated positive and negative charges.

zymogen: An inactive precursor of an enzyme; for example, pepsinogen, the precursor of pepsin.

fatty acid synthase (FAS), **745**, 746f, 747f
  acetyl and malonyl group transfer to, 747–748, 749f
  cellular location of, 750–751, 751f
  multiple active sites of, 747, 747f
  repeating reactions of, 745–747, 746f, 747f, 748–750, 749f, 750f
  structure of, 745, 746f
fatty acid synthesis
  acetyl group shuttling for, 751–752, 753f
  in chloroplasts, 750–751, 751f
  in cytosol, 750–751, 751f
  desaturation after, 754–755, 755f, 756b–757b
  fatty acid synthase active sites for, 747, 747f
  fatty acid synthase reactions in, 745, 746f, 747, 747f, 748–750, 749f, 750f
  long-chain, 753, 754f
  malonyl-CoA formation for, 744–745, 745f
  overview of, 616f
  palmitate, 747f, 748–750, 750f
  regulation of, 752–753, 753f
  repeating reaction sequence used in, 745–747, 746f, 747f, 748–750, 749f, 750f
fatty acids, **341**
  activation of, 603–606, 605f, 606f
  digestion of, 602–603, 602f
  double bonds in, 341–343
  essential, 754
  ether-linked, 349, 349f, 768, 771f
  gluconeogenesis and, 538
  in glycerophospholipids, 346–348
  ketone bodies from, 619–621, 619f, 620f
  in liver, 850–851, 851f
  mobilization of, 603, 604f, 605f
  nomenclature for, 342, 342t, 343
  partial hydrogenation of, 345, 345f
  pyruvate kinase regulation by, 544, 544f
  as storage lipids, 347f
    as hydrocarbon derivatives, 341–344, 342t, 343f
    triacylglycerols, 344–345, 344f
    waxes, 345–346, 346f
  structure and properties of, 342t, 343, 343f
  transport of, 603–606, 605f, 606f
fatty acyl-carnitine, 605
fatty acyl-CoA dehydrogenase, 607f
  genetic defects in, 616–617
fatty acyl-CoA desaturase, **754**, 755f
fatty acyl-CoA synthetases, **603**
fatty acyl-CoAs, **604**
  β-oxidation of, 609f
  formation of, 485, 603–604, 605f
  transport of, 605–606, 606f
  in triacylglycerol and glycerophospholipid synthesis, 760, 761f
favism, 548b

  synthesis of. *See* glycogenesis
glycogen phosphorylase, 477b, 522, **522**, 522f
  allosteric and hormonal regulation of, 565–567, 565f, 566f
  glycogen breakdown by, 558–559, 558f, 559f
  regulation of, 217–218, 218f, 223
glycogen phosphorylase *a*, **565**, 565f, 566, 566f
glycogen phosphorylase *b*, **565**, 565f, 566, 566f
glycogen storage diseases, 561b–562b
glycogen synthase, **562**, 563f
  phosphorylation and dephosphorylation of, 565–567, 567f, 568f
  phosphorylation of, 218
glycogen synthase *a*, **567**, 567f, 568f
glycogen synthase *b*, **567**, 567f, 568, 568f
glycogen synthase kinase 3 (GSK3), 435, 436f, **567**
  autoinhibition of, 440, 440f
  glycogen synthase regulation by, 567f, 568, 568f
  insulin actions mediated by, 567–568, 568f
glycogen-branching enzyme, **563**, 563f
glycogenesis
  in bacteria, 733
  glycogenin in, 563–565, 564f
  regulation of
    allosteric and hormonal regulation of glycogen phosphorylase, 565–567, 565f, 566f
    allosteric and hormonal signals in global carbohydrate metabolism, 568–570, 569f, 570f
    GSK3 mediation of insulin, 567–568, 568f
    phosphorylation and dephosphorylation of glycogen synthase, 565–567, 567f, 568f
    PP1 role in, 568, 569f
  UDP-glucose in, 560–563, 563f
glycogenin, **563**–565, 563f, 564f
glycogenolysis
  glucose 1-phosphate fates after, 559–560, 559f
  glycogen phosphorylase catalysis of, 558–559, 558f, 559f
  regulation of
    allosteric and hormonal regulation of glycogen phosphorylase, 565–567, 565f, 566f
    allosteric and hormonal signals in global carbohydrate metabolism, 568–570, 569f, 570f
    GSK3 mediation of insulin, 567–568, 568f
    phosphorylation and dephosphorylation of glycogen synthase, 565–567, 567f, 568f
    PP1 role in, 568, 569f
glycogen-targeting proteins, **568**, 569f
glycolate pathway in, **727**
glycolipids, **248**, 253, 253f, **346**, 347f, **349**
glycolysis, 510–**511**, 510f
  aerobic, 525
  bioenergetics of, 534, 535t, 537, 537t
  coupling of ATP and NADH formation to, 513–514
  feeder pathways for
    glycogen and starch, 522, 522f
    monosaccharides, 522f, 523–525, 524f
    polysaccharides and disaccharides, 522f, 523–525
  gluconeogenesis steps shared with, 534, 534f
  glucose 1-phosphate entry into, 559–560, 559f
  glucose 6-phosphate partitioning between pentose phosphate pathway and, 551, 551f
  glycerol entry into, 605f
  in liver, 849, 850f
  net ATP gain in, 521
  payoff phase of, 512f, 513, 518–521
    conversion of 3-phosphoglycerate to 2-phosphoglycerate, 513f, 520, 520f
    dehydration of 2-phosphoglycerate to phosphoenolpyruvate, 513f, 520–521
    oxidation of glyceraldehyde 3-phosphate to 1,3-bisphosphoglycerate, 513f, 518, 525f
    phosphoryl transfer from 1,3-bisphosphoglycerate to ADP, 513f, 518–520
    transfer of phosphoryl group from phosphoenol pyruvate to ADP, 513f, 521
  phosphorylated intermediates in, 514
  preparatory phase of, 511–513, 512f
    cleavage of fructose 1,6-bisphosphate, 513f, 516, 517f
    conversion of glucose 6-phosphate to fructose 6-phosphate, 513f, 515–516, 515f
    interconversion of triose phosphates, 513f, 516–518, 518f
    phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate, 513f, 516
    phosphorylation of glucose, 513f, 514–515
  pyruvate formed by, 510–511, 510f, 512f
    energy remaining in, 514
    fates of, 525f
    by phosphoryl group transfer from phosphoenolpyruvate to ADP, 513f, 514–515
  regulation of, 527b–528b, 539
    ATP in allosteric inhibition of pyruvate kinase, 544, 544f
    conversion of pyruvate to phosphoenolpyruvate, 544–545, 544f
    fructose 2,6-bisphosphate in allosteric regulation of PFK-1 and FBPase-1, 542, 543f
    gluconeogenesis coordination with, 539
    hexokinase isozyme responses to glucose 6-phosphate, 539–541, 539f, 540b
    reciprocal regulation of PFK-1 and FBPase-1, 541–542, 541f, 542f
    transcriptional regulation of number of enzyme molecules, 545–546, 545t, 546f
    xylulose 5-phosphate as key regulator in, 543–544
  in tumors, 526, 527b–528b
glycolysis and gluconeogenesis coordination, 27

phe operon, 1068
phenotype, **886**
phenotypic function, **317**
phenylalanine, 74s, **75**, 75f, **647**, **812**
  biosynthesis of, 811–812, 814f
  catabolism of, 640, 640f, 647–648, 647f, 648f, 649f
    defects in, 646t, 647–648, 649f
  plant substances derived from, 820–821, 822f
  properties and conventions associated with, 73t
phenylalanine ammonia lyase, 650
phenylalanine hydroxylase, **649**, 649f, **812**
phenylbutyrate, for urea cycle defects, 638, 639f
phenylketonuria (PKU), 646t, **649**–650, 649f
phenylpyruvate, **649**, 649f
pheophytin, **708**
pheophytin-quinone reaction center, 708–710
  electron transfers in, 708, 708f
  functional model of, 708f, 709
  structure of, 708f
phosphagens, **488**
phosphate, P$_i$-triose phosphate antiport system and, 724–725, 724f
phosphate buffer system, 61–62
phosphate esters, 294f
phosphate translocase, **683**, 683f
phosphatidic acid, **760**
  glycerophospholipids as derivatives of, 346–348, 347f, 348f
  synthesis of, 760, 761f, 764–765, 764f
phosphatidic acid phosphatase, **760**, 761f
phosphatidylcholine, 348f, 351f, 369f, 370, **765**
  membrane curvature and, 382
  synthesis of, 767–768, 767f, 770f
  transbilayer movement of, 378
phosphatidylethanolamine, 348f, 371f, **765**
  synthesis of, 766f, 767–768
  transbilayer movement of, 378
phosphatidylglycerol, 348f, 370f, **765**
  synthesis of, 765, 766f, 767, 768f, 769f
phosphatidylinositol, synthesis of, **765**, 768f
phosphatidylinositol 3,4,5-trisphosphate (PIP$_3$), 370f, 421f
  in INSR signaling, 435–437, 436f
  signaling role of, 354–355
phosphatidylinositol 4,5-bisphosphate (PIP$_2$), 348f
  as intracellular signal, 354, 354f
  on membranes, protein binding to, 375
phosphatidylinositol kinases, **765**, 768f
phosphatidylinositol transfer proteins, 378, **379**
phosphatidylinositols, as intracellular signals, 354–355, 354f
phosphatidylserine, 348f, 370f, 371f, **765**
  synthesis of, 765, 766f, 767–768, 767f, 769f
  transbilayer movement of, 378
phosphoanhydride bonds, 294f
phosphocreatine (PCr), 487, **819**
  biosynthesis of, 819, 821f
  free energy of hydrolysis of, 481, 481t, 482f
  in muscle, 854, 854f, 856b–857b
phosphodiester bond hydrolysis, 995
phosphodiester bonds, 765f, 998
phosphodiester linkages, **267**
  in nucleic acids, 267–268, 267f
phosphodiesterase (PDE), 423b
  in vision signaling, 429f, 430–431, 430b, 430f
phosphoenolpyruvate (PEP), **520**
  amino acid biosynthesis from, 811, 811f, 814f
  free energy of hydrolysis of, 481, 481f, 481t
  in gluconeogenesis, 534–537, 535f, 536f
  in glycolysis, 512f, 513f, 520–521
  in glyoxylate cycle, 736, 736f
  hydrolysis of, 481f
  pyruvate conversion to, 534–537, 535f, 536f
    regulation of, 544–545
phosphoenolpyruvate (PEP) carboxylase, **535**, **730**
  in C$_4$ pathway, 729f, 730
  in gluconeogenesis, 535, 535f
  in glyceroneogenesis, 762, 762f, 763f
  oxaloacetate produced by, 590, 591f
phosphofructokinase-1 (PFK-1), **516**
  in glycolytic pathway, 513f, 516
  regulation of
    by citrate, 689
    by fructose 2,6-bisphosphate, 542, 543f
    reciprocal, 541–542, 541f, 542f
phosphofructokinase-2 (PFK-2), **542**, 543f, 734, 734f
phosphoglucomutase, **522**, **559**, 559f
6-phosphogluconate dehydrogenase, **548**
  in pentose phosphate pathway, 547f, 548
phosphogluconate pathway, **546**. *See also* pentose phosphate pathway
phosphoglucose isomerase, **515**
  in glycolytic pathway, 513f, 515–516, 515f
2-phosphoglycerate (2-PGA)
  enolase dehydration of, 210, 211f
  in glycolytic pathway, 513f, 520–521, 520f
3-phosphoglycerate, **519**, **719**
  amino acid biosynthesis from, 806–809, 807f, 808f
  in Calvin cycle, 720f, 721–722
  CO$_2$ fixation into, 720–721, 724f, 728f
  conversion to glyceraldehyde 3-phosphate, 720f, 721–722
  in glycolate pathway, 727–729, 728f
  in glycolytic pathway, 513f, 520, 520f
  P$_i$-triose phosphate antiport system and, 724–725, 725f, 726f
  in starch synthesis, 734, 735f
  in sucrose synthesis, 734f
3-phosphoglycerate kinase, 721
phosphoglycerate kinase, **518**–519, 726f
  in glycolytic pathway, 513f, 521
phosphoglycerate mutase, **520**
  in glycolytic pathway, 513f, 520, 520f
phosphoglycerides. *See* glycerophospholipids
2-phosphoglycolate, **727**
  in glycolate pathway, 727–729, 728f
phosphoglycolohydroxamate, 203f
phosphohexose isomerase, **515**
  in gluconeogenesis, 515f
  in glycolytic pathway, 513f, 515–516, 515f
phosphoinositide 3-kinase (PI3K), 435, 436f, 437f
phospholipase C (PLC), **425**
  in GPCR signaling, 425, 427f
  membrane analysis using, 373f
phospholipases, 352, 352f
phospholipids, **346**, 347f
  biosynthesis of, 764–770
  glycerophospholipids. *See* glycerophospholipids
  lysosome degradation of, 352, 353b
  membrane bilayer of, 367–368, 369f, 370f

    CDP-diacylglycerol in, 765–767, 766f, 768f
    eukaryotic pathways to phosphatidylserine, phosphatidylethanolamine, and phosphatidylcholine, 767–768
    plasmalogen, 768, 771f
    precursors for, 760, 761f
    sphingolipids, 770, 772f
    transport to cellular membranes after, 770
  transbilayer movement of, 378–379, 378f
phosphomannose isomerase, 522f
4′-phosphopantetheine, **747**
phosphopentose isomerase, **548**
  in pentose phosphate pathway, 547f, 549
phosphoprotein phosphatase 1 (PP1), **418**, **567**
  as central regulator in glycogen metabolism, 568, 569f
  glycogen phosphorylase regulation by, 217–218, 218f
  glycogen synthase regulation by, 567, 567f, 568f
phosphoprotein phosphatase 2A (PP2A), 545, 546
phosphoprotein phosphatases, **217**, 220
  in β-adrenergic signaling termination, 417–418
phosphoproteins, 83t
phosphoramidite method, DNA synthesis using, 283, 284f
5-phosphoribosyl-1-pyrophosphate (PRPP), **806**, 806s
  histidine biosynthesis from, 814, 815f
  purine biosynthesis from, 825–827, 825f, 826f
  pyrimidine biosynthesis from, 827–829, 828f
5-phosphoribosylamine, **825**, 826f
phosphorolysis, 558–559, 586f
  of glycogen and starch, for glycolysis, 520, 522, 522f
phosphoryl group, 475–476, 476f, 484–485, 484f
  glycolysis role of, 514
phosphoryl group transfers, 475–476, 476f
  from 1,3-bisphosphoglycerate to ADP, 513f, 518–520
  ATP and
    in assembly of informational macromolecules, 485–487
    energy provided by, 482–484, 483f
    free-energy change for ATP hydrolysis, 479–481, 479f, 480t
    in muscle contraction, 483, 487
    phosphorylated compounds and thioesters with large free energies of hydrolysis, 481–482, 481f, 481t, 482f
    reactions involved in, 484–485, 484f, 486b
    in transphosphorylations between nucleotides, 487–488, 487f
  from phosphoenolpyruvate to ADP, as last step in glycolysis, 513f, 521
phosphorylase *b* kinase, 427, **566**
  glycogen phosphorylase activation by, 565, 565f, 566f
phosphorylase kinase, glycogen phosphorylase regulation by, 218, 218f

  altered, 312–313, 312f

alternative splicing and, 981–983, 983f
amino acids in, 9f, 13, 72, 80–83, 82t, 83t
amplified production of
  altered, 312–313, 312f
  bacteria systems used for, 310, 310f
  expression vectors for, 309, 310f
  insect and insect virus systems used for, 311–312, 311f
  mammalian cell systems used for, 312
  tags for purification of, 313–314, 313t, 314f
  yeast systems used for, 310–311
cellular concentration of, 1054, 1055f
characterization of, 87–89, 87f, 88f, 89f
chemical groups in, 83, 83t
chemical synthesis of, 95–96, 97f
degradation of
  in liver, 850–851, 850f
  in metabolic regulation, 499f, 499t
  oxidation and urea production. *See* amino acid catabolism
  specialized systems mediating, 1048–1049, 1048f, 1049t
denaturation of, 128–136, 129f
  loss of function with, 129–130, 129f
  renaturation after, 130, 130f
digestion of, 627–628, 628f
DNA encoding of, 29–30, 29f
as electron carriers, 492–494
enzymes as, 178–179. *See also* enzymes
folding of, 128–136, 129f
  amino acid sequence role in, 130, 130f
  assisted, 132–133, 132f
  computational chemistry and, 138b–139b
  defects in, 133–135, 133f, 134b–135b
  as final step of synthesis, 1015, 1016f, 1016t, 1036–1039, 1037f
  stepwise process of, 131–132, 131f, 132f
fusion, 313
  for immunoprecipitation, 320–321, 321f
  protein localization with, 319–320, 319f, 320f
  for yeast two-hybrid analysis, 321–322, 322f
glycosylation of, 252–253, 252f
half-life of, 499t, 1049, 1049t
homologous, 99
in immune response, 164–165
localization of, 318–320, 318f, 319f, 320f
in membranes. *See* membrane proteins
modular, 409
molecular weight estimation of, 88, 88f
motor. *See* motor proteins
mRNA coding for, 274–275, 276f
naming conventions of, 914–915
oxygen-binding. *See* oxygen-binding proteins
pI of, determination of, 88, 89f
purification of, 84–87, 84f, 85f, 87t
  immunoprecipitation, 320–321, 321f
  tags for, 313–314, 313t, 314f
quantification of, 89–90, 90f
regulatory, 214
  in development, 1087–1089, 1087f, 1088f, 1089f, 1090f
  DNA-binding domains of, 1060–1063, 1060f, 1061f, 1062f, 1063f
  protein-protein interaction domains of, 1063–1065, 1064f
ribosomal, 1070–1071, 1070f, 1071f
scaffold, 409, 439–442, 439f, 440f, 441f
separation of
  column chromatography, 84–87, 84f, 85f, 87t
  dialysis, 84
  electrophoresis, 87–89, 87f, 88f, 89f
sequencing of, 91, 92f
  classical-based methods for, 92–93, 92f, 92t, 93f
  mass spectrometry methods for, 93–95, 94f, 95f
signaling
  GPCRs. *See* G protein–coupled receptors

Resources

Abbreviations for Amino Acids

A	Ala	Alanine	N	Asn	Asparagine
B	Asx	Asparagine or aspartate	P	Pro	Proline
			Q	Gln	Glutamine
C	Cys	Cysteine	R	Arg	Arginine
D	Asp	Aspartate	S	Ser	Serine
E	Glu	Glutamate	T	Thr	Threonine
F	Phe	Phenylalanine	V	Val	Valine
G	Gly	Glycine	W	Trp	Tryptophan
H	His	Histidine	X	—	Unknown or nonstandard amino acid
I	Ile	Isoleucine			
K	Lys	Lysine	Y	Tyr	Tyrosine
L	Leu	Leucine	Z	Glx	Glutamine or glutamate
M	Met	Methionine			

Asx and Glx are used in describing the results of amino acid analytical procedures in which Asp and Glu are not readily distinguished from their amide counterparts, Asn and Gln.

The Standard Genetic Code

UUU	Phe	UCU	Ser	UAU	Tyr	UGU	Cys
UUC	Phe	UCC	Ser	UAC	Tyr	UGC	Cys
UUA	Leu	UCA	Ser	UAA	Stop	UGA	Stop
UUG	Leu	UCG	Ser	UAG	Stop	UGG	Trp
CUU	Leu	CCU	Pro	CAU	His	CGU	Arg
CUC	Leu	CCC	Pro	CAC	His	CGC	Arg
CUA	Leu	CCA	Pro	CAA	Gln	CGA	Arg
CUG	Leu	CCG	Pro	CAG	Gln	CGG	Arg
AUU	Ile	ACU	Thr	AAU	Asn	AGU	Ser
AUC	Ile	ACC	Thr	AAC	Asn	AGC	Ser
AUA	Ile	ACA	Thr	AAA	Lys	AGA	Arg
AUG	Met*	ACG	Thr	AAG	Lys	AGG	Arg
GUU	Val	GCU	Ala	GAU	Asp	GGU	Gly
GUC	Val	GCC	Ala	GAC	Asp	GGC	Gly
GUA	Val	GCA	Ala	GAA	Glu	GGA	Gly
GUG	Val	GCG	Ala	GAG	Glu	GGG	Gly

*AUG also serves as the initiation codon in protein synthesis.

Unit Abbreviations

A	ampere	L	liter
Å	angstrom	M	molar (concentration)
atm	atmosphere	m	meter
°C	degree Celsius	min	minute
cal	calorie	mm Hg	millimeters of mercury (pressure)
cpm	counts per minute	mol	mole
Da	dalton	*N*	normal (concentration)
dpm	disintegrations per minute	Pa	pascal
F	faraday	r	revolution
g	gram	S	Svedberg unit
h	hour	s	second
J	joule	V	volt
K	kelvin	yr	year

Prefixes

10^{9}	giga	G
10^{6}	mega	M
10^{3}	kilo	k
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f

Some Conversion Factors

Length	$1\text{ cm} = 10\text{ mm} = 10^{4}\ \mu\text{m} = 10^{7}\text{ nm}$ $= 10^{8}\ \text{Å} = 0.394\text{ in}$ $1\text{ in} = 2.54\text{ cm}$ $1\text{ yard} = 0.9144\text{ meters}$ $1\text{ mile} = 1.609\text{ kilometers}$
Mass	$1\text{ g} = 10^{-3}\text{ kg} = 10^{3}\text{ mg} = 10^{6}\ \mu\text{g}$ $= 3.53 \times 10^{-2}\text{ oz}$ $1\text{ oz} = 28.3\text{ g}$
Temperature	$°\text{C} = 5/9(°\text{F} - 32)$ $\text{K} = °\text{C} + 273$
Energy	$1\text{ J} = 10^{7}\text{ erg} = 0.239\text{ cal}$ $1\text{ cal} = 4.184\text{ J}$
Pressure	$1\text{ torr} = 1\text{ mm Hg} = 1.32 \times 10^{-3}\text{ atm}$ $= 1.333 \times 10^{2}\text{ Pa}$ $1\text{ atm} = 758\text{ torr} = 1.01 \times 10^{5}\text{ Pa}$

Some Physical Constants, with Symbols and Values

Atomic mass unit (dalton)	amu	1.661×10^{-24} g
Avogadro's number	*N*	6.022×10^{23}/mol
Boltzmann constant	**k**	1.381×10^{-23} J/K; 3.298×10^{-24} cal/K
Faraday constant	*F*	96,480 J/V • mol
Gas constant	*R*	1.987 cal/mol • K; 8.315 J/mol • K
Planck's constant	*h*	1.584×10^{-34} cal • s; 6.626×10^{-34} J • s
Speed of light (in vacuum)	*c*	2.998×10^{10} cm/s

ON THE COVER:

In this artistic rendering, a protocell composed of a bilayer of fatty acids surrounds an aqueous compartment containing an RNA ribozyme and nucleic acids. Protocells are used by biochemists to explore reactions that could mimic those that led to the origin of life on Earth. Billions of years ago, hydrophobic molecules may have formed cell-like assemblies like protocells in which molecules capable of replicating themselves could be concentrated and protected from the external environment. These likely provided the origins of the membranes, nucleic acids, and catalysts found in today's cells.

BUDGET BOOKS This book does not have a traditional binding; its pages are loose and 3-hole punched to provide flexibility and a low price to students.
